The Dangers of the Electric Current.—In the Archives d'électricité médicale expérimentale et cliniques for March 15th there is an abstract of a report of the proceedings of the Société de biologie in which M. d'Arsonval remarks that in a previous communication he established the fact that the electric currents employed, whatever their intensity, caused only a condition of apparent death which was due to arrest of the heart's action, and in an accident of this kind it was sufficient to practice artificial respiration in order to resuscitate the patient. He relates the following case to prove the soundness of this opinion: A criminal, who was recently "electrocuted" in America, received a current of 4,000 volts, which was 3,000 volts more than had been used in preceding executions. In spite of the high voltage the current produced only a condition of apparent death, for on practicing artificial respiration with a pair of bellows in the trachea the victim was resuscitated. [We should like to know when and precisely where this happened.]

The conclusion, says M. d'Arsonval, must be drawn from this fact is, that the employment of electricity for executions must be given up. It is generally believed, he says, that the alternating current is more dangerous than the continuous current. On the contrary, the accidents caused by the continuous current at the high power used by manufacturers are nearly always fatal, the cause of death being due to the electrolytic phenomena which accompany the current. The living body, in reality, is not a homogeneous conductor, and the polar action is produced not only at the points of entrance and of departure of the current, but at the surface of each different tissue crossed by the current.
M. Chauveau remarked that he had pointed out the existence and the danger of the electrolytic phenomena produced in the close connection of all the tissues during the passage of the electric current. M. Laborde related the case of a workman who had been restored to life by rhythmic traction on the tongue at the end of an hour after having received an alternating current of 2,000 volts. M. Dastre remarked that this restoration was the rule every time when the heart or the respiration was arrested if there was no destructive organic lesion, whatever might be, for that matter, the causes of this suspension of the cardiac or respiratory functions.

M. Chauveau remarked that there was, however, an important distinction to be made, in view of the possibility of resuscitation, between subjects in a state of syncope and those in a state of asphyxia. The first might be restored at the end of a few hours; the latter, on the contrary, at the end of a comparatively short time, not more than a few minutes, were refractory to all attempts at resuscitation.

**Dislocation of the Head of the Humerus complicated with Impacted Fracture of its Anatomical Neck.**—At a recent meeting of the Philadelphia Academy of Surgery Dr. John B. Roberts reported a case as follows:

"A boy, nine years old, was brought to my clinic at the Women's Hospital on February 22, 1895, by Dr. Marie K. Formad, on account of an injury to his left shoulder. About a week before Dr. Formad saw the boy professionally, and ten days before I had an opportunity to examine him, he had fallen at school and struck the shoulder against a wall.

"He had been brought to the hospital two days before I saw him, and Dr. Anna M. Fullerton, with Dr. Formad, examined him under ether, and reduced what seemed to be subcoracoid dislocation of the head of the bone. Both of these physicians were struck by the flattened appearance of the deltoid region, and say that the bone distinctly snapped into place during the manipulations which they made. They could subsequently put the boy's hand on his head and on the opposite shoulder. These positions could not be given the bone before etherization and reduction of the dislocation. The shoulder had still, however, an unusual appearance, notwithstanding the reposition of the luxated bone. The case was accordingly referred to me.

"When I saw him the acromion was unduly prominent. The left humerus was apparently half an inch shorter than the right, and the width of the upper end was markedly increased. The greater tuberosity, which could be easily felt, for the boy was not very fat, rotated when the lower end of the humerus was grasped and given a rotary motion. The head of the bone, which I could feel in its normal position, also moved during this manipulation. I felt at times a grating like that of crepitus, but this did not seem to pertain to the humerus so much as to the scapula. It seemed to be in the posterior portion of the joint; but I could make out no fracture of the neck of the scapula, as was suggested by the situation of the grating.

"The boy could voluntarily move his arm upward and outward without pain, though these movements were made in a guarded and careful manner, as though he feared suffering. The movements were not very extensive, but showed that the continuity of the humerus was maintained.

"Being unable to make a diagnosis without giving pain I etherized him. I then found that rotation of the lower end of the humerus caused similar motion of the head of the bone, but that if I held the head still with my left hand I could, by means of my right hand holding the shaft of the humerus, cause a bending or rocking motion between the head and the shaft. This movement was between the greater tuberosity and the head. It was apparent that there existed a connection between the shaft and the tuberosity, and also between these portions of the bone and the head; but an antero-posterior rocking motion could be made between the shaft and tuberosity on the one hand and the head on the other. There was no fracture of the neck of the scapula and no dislocation of the head of the humerus.

"Three conditions were suggested by these symptoms: First, a firmly impacted fracture at or near the anatomical neck, which allowed the whole bone to move when rotary motions were given to the shaft of the humerus, but which permitted bending between the head and greater tuberosity. Second, a partial or green-stick fracture at or near the anatomical neck. Third, an epiphysial separation of the head with impaction. The fracture, whether impacted or of the green-stick variety, had permitted the dislocation, which also existed originally, to be reduced under ether by Dr. Fullerton and Dr. Formad. The rigidity maintained at the sent of fracture had been sufficient to permit the head of the bone to be put in place by leverage obtained from the shaft of the bone. The manipulations needed to reduce the luxation were not forcibly made, and the replacement was easily accomplished. Hence, the fracture could not have been produced by these efforts.

"The widening of the upper end of the humerus, which was very conspicuous, and the apparent shortening of the humerus, inclines me to the theory of impacted fracture. The age of the child suggested, however, a green-stick fracture as a possibility. By forcible manipulation I obtained complete separation of the fragments. The sensation imparted to my hands was that caused by disentangling or breaking apart two pieces of bone. Subsequently the arm assumed the usual appearance of a fracture of the humerus close to the shoulder joint. The crepitation originally felt in the vicinity of the scapula was probably due to the rough edges of the firmly impacted fracture rubbing against the border of the glenoid cavity. Having become convinced of the diagnosis, and having restored the proper conformation of the shoulder, I dressed the injury in the usual way—with a small pad in the axilla and a bandage to hold the arm to the thorax, which acted as an internal splint. . . . Union took place promptly. When I last saw the boy, about eight weeks after my first examination, there was a little unnatural prominence of the acromion, and the head of the humerus seemed to project forward a little more than usual. These appearances may have been due to atrophy of the deltoid. The movements of the joint were perfect."

The American Neurological Association will hold its twenty-first annual meeting in Boston on June 5th, 6th, and 7th. The preliminary programme includes the following papers: Insanity and Phthisis, their Concurrence, Coexistence, and Transmutation, by Dr. H. A. Tomlinson, of St. Peter; The "Etiology of Obstetrical Paralysis, by Dr. George L. Walton, of Boston; A Lantern Exhibition of Photographs of Nervous Histology, by Dr. I. Gorgi, of New York; A Contribution to the Pathology and Morbid Anatomy of Amyotrophic Lateral Sclerosis, by Dr. Joseph Collins, of New York; The Conservative Value of the Play Impulse, by Dr. Irving C. Rose, of Washington; Must Acute Paranoia be admitted into our Nomenclature? by Dr. William Noyes, of Foxboro; Antonomization, by Dr. Smith Baker, of Utica; A Case of Hereditary Chorea, with Autopsy, by Dr. Charles L. Dana, of New York; Cases of Brain Tumor—A Case of Total Hysterical Amnesia in the Male, by Dr. George J. Preston, of Baltimore; Telegrapher's Paralysis, by Dr. James Hendrie Lloyd, of Philadelphia; The Diagnosis of Hemorrhagic Cerebral Pachymeningitis, by Dr. William N. Bullard, of Boston; The Asso-
cation of Tabes and Paralytic Dementia, by Dr. Theodore Diller, of Pittsburgh; The Localization of Small Gross Lesions in the Pons and Pneumoblasta, by Dr. Charles K. Mills, of Philadelphia; A Report of a Case of Peroneal Muscular Atrophy, with Autopsy, by Dr. William C. Krauss, of Buffalo; The Home Treatment of Insanity, by Dr. H. M. Bannister, of Chicago; The Criminal Insane Abroad, by Dr. C. Eugene Riggs, of St. Paul; A Report of a Case of Tumor of the Cerebellum, with Autopsy—Operation by Dr. John F. Erdmann, by Dr. E. D. Fisher, of New York; Hyperostosis Cranii (Megalacephaly), with Illustrations, by Dr. James J. Putnam, of Boston; The Pulse in Insanity—Original Study of Cases, by Dr. Theodore H. Kellogg, of Willard; A Report of a Case of Multiple Nenritis in an Infant, by Dr. Greene M. Hammond, of New York; Two Cases of Railway Spine, with Autopsy, by Dr. F. X. Dercum, of Philadelphia; Fissural Studies: (a) Two Philosophers, (b) An Apparent Duplication of the Central Fissures, by Dr. Burt G. Wilder, of Ilion; Pseudo-neurasthenia, by Dr. Morton Prince, of Boston; Hysterical Amblyopia and Amanrosis—A Report of Five Cases Treated by Hypnotism, by Dr. J. Arthur Booth, of New York; Exhibition of the Brain of a Chimpanzee, by Dr. Thomas Dwight, of Boston; and The Part of Inhibition in the Physiology of Respiration, by Dr. William T. Porter, of Boston.

Are there Seasons Unfavorable for Surgical Operations?

In the Medical Record for April 27th there is an article on this subject by Dr. Robert Abbe, who remarks that this is a question often asked of the surgeon by patients, and it is one, he says, that is worthy of consideration. There are many operations, not urgent, which have been followed by grave consequences and sometimes death, and the question has been asked, Would it have been wiser to wait for a better season?

The public mind, says Dr. Abbe, has had the idea that there is a difference in relative danger at varying seasons, and we have all been conscious of extended periods of depressing weather and heavy, gloomy days when we work with difficulty. The public also knows that at certain hours of the night the vital powers are at an ebb; that there are seasons when sudden deaths seem to prevail; that epidemics of grippe, etc., come at times and close our schools—when the general health seems to be below par. Naturally, then, the inference is, that if patients are to be operated on, they will choose the best season.

Seasons, says the author, undoubtedly act with varying power on different persons. The highest state of the functions of the body—respiratory, muscular, etc.—is in the spring, through summer, and toward autumn. After that the baro-nic acid vapor exhaled, the volume of air inspired, etc., all lessen, autumn representing the minimum of normal functional activity, as is shown by most careful physiological experiments. In the spring the system is alive to changes, and it is reasonable to say that an increased reparative power may be looked for. This is seen in every chronic case in the hospitals during the spring and early summer. Dr. Abbe thinks that the improvement may be due somewhat to the admission of air to the rooms and to the increase in sunshine. Nevertheless, he says, the spring offers a helpful power to the surgeon, not only in the recuperative physical action of the body, but in the increased mental attitude of convalescents who enjoy the sunshine.

Traumatic fever does not seem to be more intense in hot weather, and the septic febrile exacerbations so constantly regarded as malarial at one time, and for which quinine is so often given when the kind should be used to evacuate hidden pus, has been spoken of often as to be looked for in the autumn season. There is often a tendency, says Dr. Abbe, for work to run in groups. For example, four or six cases of tuberculosis will occur during a certain month of the year, then months will pass without another case occurring. The same experience applies to diffuse phlegmonous inflammations, carbuncules, supplicative ear troubles, purulent tonsillar inflammation, etc. There are months when these diseases prevail; not the hot months, although we should expect bacterial growth of all sorts to be favored by heat; they seem to be rather the winter and spring months, when, from bad housing or epidemic aerial influence, the season seems to breed disease. These causes much surgical work, but that they implicate the cases of impending operation, says Dr. Abbe, is entirely another question. If, during the months of January and February, the cases of appendicitis of a virulent type prevail and pneumonia, grippe, diphtheria, and erysipelas are more numerous, does it, he asks, call for a check of surgical work in cases that can be postponed, such, for example, as laparotomies, operations for lipomatosis, hemorrhoideal, or calculus, urethral work, ovariotomy, etc.? That can be answered by considering the death list in surgical cases at different seasons, and, so far as the author can discover from his own work, he finds that the best results ran uniformly through these months.

With regard to pneumonia complicating surgical work, Dr. Abbe says that his experience has been quite negative. This complication as a sequel of operation is now recognized, he says, as due to preventable causes in most cases, and is seen more in certain classes of work where inhalation of impure or septic particles has given rise to septic pneumonia. In the general surgical wards of the hospitals the author’s experience is that pneumonia is extremely rare, since he has provided for ample warmth and protection for the patient during and after operation and for the preventable septic infection from vomit and inhalation by washing out the stomachs of hernia patients and the liberal use of iodiform packing and borax acid in the mouth, the throat, and the nose. Dr. Abbe feels that pneumonia, or so-called pneumonia, after surgical work, which has been sometimes considered a seaseasonable complication, is really preventable, and that even when there is a prevailing epidemic a given number of surgical patients are even less likely to suffer from it than a corresponding number of the community at large, because they are protected by being in equable surroundings.

The argument, then, says the author, for both children and adults is in favor of ignoring the season, for the experience of the surgeons of to-day will show that, as an illustration of traumatism, the conduct and results of fractured bones are entirely independent of the season, and for all practical purposes any properly conducted surgical operation, with aseptic work, and the wound covered in by aseptic dressings, is equivalent to a subcutaneous wound, which proceeds as harmlessly as a simple fracture. We may feel, then, says Dr. Abbe, that we are in a position to say to a patient, “It is as well to do it now as at any other time.” For his part, he says it is a satisfaction to dispel the delusion that this might not be true, concerning which he has heretofore had a slight doubt.

The Medical Society of the State of North Carolina.—The forty second annual meeting was held at Goldsboro on May 14th, 15th, and 16th, under the presidency of Dr. John H. Tucker, of Henderson. The programme included the following papers: Diphtheria Antitoxine, by Dr. Albert Anderson; Non-penetrating Abdominal Injuries, by Dr. Robert S. Young, of Concord; The Anatomy of Hernia, with Reference to Macalwau’s Operation, by Dr. R. H. Whitehead, of Chapel Hill; Anesthesiá, by Dr. J. G. Blount, of Washington; A New Method of applying Plaster-of-Paris Dressing in Fractures, by Dr. H. A.
The Medical Society of the State of Pennsylvania.—The forty-fifth annual meeting will be held at Chambersburg on May 21st, 22d, 23d, and 24th, under the presidency of Dr. John B. Roberts, of Philadelphia. The programme includes the following papers:

Address in Medicine, by Dr. I. C. Gable, of New York; The Sequel of Typhoid Fever, by Dr. T. D. Dunn, of West Chester; The Treatment of Malignant Tumors by the Toxins of Erysipelos, by Dr. John B. Roberts, of Philadelphia; The Treatment of Typhoid Fever, by Dr. James Tyson, of Philadelphia; The Prophylaxis of Pneumonia in Women, by Dr. J. M. Babby, of Philadelphia; Tuberculosis, by Dr. John M. Batten, of Pittsburgh; The Treatment of Fistula in Ano by Lange’s Method, or Immediate Suture of the Tract, by Dr. Lewis H. Adler, Jr., of Philadelphia; Ocular Affections Associated with Littorelia, by Dr. Samuel D. Riskly, of Philadelphia; Experience in the Treatment of Diphtheria during Thirty-four Years of Practice, by Dr. William S. Stewart, of Philadelphia; Acute and Chronic Cystitis, by Dr. J. W. Roop, of Harrisburg; The Treatment of Nausea, by Dr. H. R. Wharton, of Philadelphia; A Report of One Hundred and Twenty-five Cases of Hernia in which the Radical Cure was Performed, by Dr. Ernest Lacle, of Philadelphia; Ten Minutes in Medical Electricity, by Dr. George S. Bull, of Chambersburg; The Present Status of the Sanitary Movement for the Adoption of the Individual Commissary Cup, by Dr. H. S. Anders, of Philadelphia; An Address in Hygiene, by Dr. Hildegarde H. Longsdorf, of Carlisle; The Prevention and Cure of Tabo-ovarian Inflammation, by Dr. G. Betton Massay, of Philadelphia; Movable Kidney, by Dr. Charles P. Noble, of Philadelphia; Oxygen Gas under High Pressure vs. Compressed Air for Spraying and Nebulizing in Diseases of the Chest, Throat, Nose, and Ear, by Dr. A. B. Kirkpatrick, of Philadelphia; The Necessity for a Static System of Registration of Vital Statistics in Pennsylvania, by Dr. Benjamin Lee, of Philadelphia; Carcinoma of the Uterus, by Dr. Thomas S. Cullen, of Baltimore; An Address in Surgery, by Dr. C. L. Stevens, of Athens; Late Syphilitic Lesions, by Dr. Edward Martin, of Philadelphia; Rupture of the Tendon of the Quadriceps Extensor Femoris, by Dr. J. J. Bachman, of Pittsburgh; Mental Influence in the Treatment of Disease, by Dr. Theodore Diller, of Pittsburgh; Ophthalmia Neonatorum, by Dr. Joseph E. Willetts, of Philadelphia; The Treatment of Typhoid Fever by Grade, by Dr. A. P. Hull, of Montgomery Station; When should Vaginal Incision be Preferred to Abdominal in the Treatment of Pelvic Disease? by Dr. E. E. Montgomery, of Philadelphia; Pharmacy in the Medical Profession, by Dr. S. S. Good, of Meyersdale; Deaf mutes—Can anything be Accomplished by Treatment? by Dr. Louis J. Lautenbach, of Philadelphia; Microbes and Molds, by Dr. William T. Dickson, of Media; A Contribution to the Clinical Study of Typhoid Fever, by Dr. Murray Galt Motter, of Lancaster; Retrolfexion of the Uterus when Chronic is Incurable except by the Application of Surgical Methods, by Dr. B. F. Baer, of Philadelphia; The Treatment of Earache, by Dr. L. W. Moyer, of East Mauch Chunk; Practical Medicine, by Dr. J. C. Channell, of Wrightsville; an address in Obstetrics, by Dr. W. R. Ulrich, of Chester; The Necessity for the Advertisement and Isolation of Certain Contagious and Infectious Diseases, by Dr. F. P. Le Moyne, of Pittsburgh; Fat in Pulmonary Consumption, by Dr. Thomas J. Mays, of Philadelphia; Massage in Surgery, by Dr. James K. Young, of Philadelphia; Ligation of Arteries in the Treatment of Malignant Disease, by Dr. John H. Packard, of Philadelphia; Carcinoma of the Uterus, by Dr. I. N. Sively, of Waynesboro; Heredity, by Dr. J. K. Garver, of Harrisburg; Epidemic Diseases, by Dr. B. L. Krechmer, of Dalmatia; The Management of Cases of Typhoid Fever, by Dr. H. G. McCormick, of Williamsport; A Case of Pyelitis in a Boy of Seven Years, by Dr. J. P. Crozer Griffith, of Philadelphia; Medical Green Goods, by Dr. John B. Donaldson, of Canonsburg; Labor at Full Term Complicated by Typhoid Fever, by Dr. William M. Findley, of Altoona; Empyema of the Mastoid and its Relation to Acute Aural Disease, by Dr. S. MacCuen Smith, of Philadelphia; an address on The Present Attitude of Physicians and Modern Medicine toward Homoeopathy, by the president; an address on Mental Disorders, by Dr. F. X. Dereme, of Philadelphia; The Diagnosis of Gastric Lesions by Modern Methods, by Dr. S. Solis-Cohen, of Philadelphia; Typhoid Fever, by Dr. George G. Groff, of Lewisburg; Undue Reliance Upon Temperature Records, by Dr. J. Chris Lange, of Pittsburgh; A Report of a Series of Cases of Laryngeal Diphtheria, Treated by Antitoxine, with and without Intubation, by Dr. Edwin Rosenthal, of Philadelphia; Another Word on Aedoneal Growth of the Pharynx, by Dr. Harrison Allen, of Philadelphia; The Value of an Alcoholic-vapor Bath in the Treatment of Suppression of Urine and Uremia, by Dr. F. S. Neville, of Kirtland; Forty Years’ Experience with Veratrum Viride, by Dr. J. L. Ziegler, of Mount Joy; A Clinical Study of the Relation of Accommodation to Convergence, by Dr. Howard F. Hansell, of Philadelphia; Nerve-muscle Atony in Girls, by Dr. Kate D. Miesz, of Easton; Aeonitine in Neuralgia, by Dr. J. Newton Hunsberger, of Slippery; The Emotional Brain, by Dr. Benjamin Lee, of Philadelphia; The Rational Treatment of Fracture of the Femur near the Hip Joint in Aged Persons, by Dr. E. V. Swing, of Coatesville; A Contribution to the Study of Deaf-mutism, by Dr. Arthur Ames Bliss, of Philadelphia; A Report on Hydrophobia, by Dr. Charles W. Dulles, of Philadelphia; an address in Otolgy, by Dr. L. H. Taylor, of Wilkesbarre; Irregular Forms of Enteric Fever, by Dr. J. C. Wilson, of Philadelphia; The Treatment of Tertiary Syphilis,
MISCELLANY.

by Dr. Orville Horwitz, of Philadelphia; Bacteriological Examinations in Medicine or Surgery, by Dr. Joseph McFarland, of Philadelphia; The Diagnosis and Treatment of Acute Intestinal Obstruction, by Dr. James M. Barton, of Philadelphia; The Relief of Some Cases of Functional Nervous Troubles by Cur- ing Eye-strain, by Dr. J. Saylor Brown, of Williamsport; Faith and Therapeutics, by Dr. H. G. Chritzman, of Welsh Run; Vaccine Virus, by Dr. H. M. Alexander of Marietta; Whither are we Drifting? by Dr. J. A. Arnold, of Arlmore; The Treatment of Typhoid Fever, by Dr. H. A. Mowery, of Marietta; Phtisis Pulmonalis, its Prevention and Cure, by Dr. A. C. Chamberlain, of Brooklyn; The Remote and Immediate Causes of Epidemic Influenza, by Dr. W. J. Kline, of Greensburgh; Auto-intoxication, with Special Reference to Certain Diseases, by Dr. A. Enfield, of Bedford; Hydrophthalmus, with a Case Treated and Cured by Tapping, by Dr. H. G. Carey, of Berlin; and Antero-fixation of the Uterus, by Dr. George Erey Shoe- maker, of Philadelphia.

The New York Academy of Medicine.—At the last regular meeting, on Thursday evening, the 16th inst., a paper entitled A Clinical and Bacteriological Study of the Gonococcus in the Male Urethra and in the Vulvo-vaginal Tract of Children was to be read by Dr. Henry Hinman.

At the next meeting of the Section in Ophthalmology and Otology, on Monday evening, the 20th inst., Dr. W. B. Johnson will read a paper entitled Suggestions regarding Legislation for the Prevention of Blindness, and Dr. H. H. Seabrook one on Accommodation in Old People. Cases and specimens will be presented.

At the next meeting of the Section in General Medicine, on Tuesday evening, the 21st inst., a paper entitled A Further Report on Aedylia Gastrica will be read by Dr. Morris Manges, and one on The Fleischig Method in the Treatment of Insane Epileptics by Dr. L. Pierce Clark. Cases will be presented.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 22d inst., Dr. W. F. Chappell will read a paper on Xerosomia, or Dry Mouth. There will be a presentation of patients, instruments, and apparatus.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 23d inst., the following papers will be read: Pregnancy and Labor complicated by Carliasis, by Dr. Julius Rosenberg; A Contribution to the Study of the Nature, Cause, and Treatment of Suspended Animation in the Newborn, by Dr. J. D. Bissell. Cases will be reported and specimens and instruments presented.

At the next meeting of the Section in Neurology, on Friday evening, the 24th inst., the following papers will be read: On the Etiology of Vertigo, by Dr. Arthur A. Boyer; The Differential Diagnosis between Localized Neuritis, Rheumatism, and such other conditions as give Similar Symptoms, by Dr. L. F. Bishop. Cases will be presented.

A Warning to Stamp Collectors.—At the present day a man in the medical world can scarcely be considered to have fully justified his existence till he has discovered a new disease, or at least some previously unsuspected source of danger to health. Dr. Unna, of Hamburg, may therefore be looked upon as doubly fortunate, for besides enriching nosology with more than one new disease, he has now made a considerable section of the human race still further his debtors by showing them that their favorite "hobby" has the added spice of danger required to make it completely delightful. Stamp collecting might at first sight appear to be a perfectly harmless mania, but here too, as in every other human pleasure or pursuit, it turns out that laetet anguis in herba. There is a disgusting disease of the hair known as piedra (stone), and listhertz considered to be peculiar to Colombia in South America, where it is comparatively common among the fair sex. Men also suffer, though to a less extent, and chiefly in their beards. Black gritty particles form on the hair shafts; they are so hard that they rattle like pebbles (hence the name) when the comb is used. An unpleasant feature of the affection is a peculiar acid smell. The concretions have been found to consist of the closely packed spores of a special fungus. The disease is supposed to be connected with a mucilaginous substance which is greatly in favor with the native beauties of Colombia for anointing their dark tresses. Dr. Unna has satisfied himself that this interesting complaint can be conveyed to Europe by a somewhat unexpected channel. He has recently had under his care a professional brother whose beard was unquestionably affected with piedra. The patient had never been near Colombia, and the question was how could he have got the disease? It turned out, however, that he often received letters from Colombia, and he was in the habit of detaching the stamps by soaking them in water. Dr. Unna conjectures that he may have inoculated himself with the fungus which causes the disease while fiddling with his beard with fingers still wet with the water in which he had soaked the stamps. The theory appears to involve the hypothesis that the "mucilagin- ous substance" which is suspected of breeding the disease is used in Colombia for gummimg stamps; but, at any rate, the case should be a warning to stamp collectors as suggesting the possibility of the importation of the germs of various innoxious diseases from their native haunts.—British Medical Journal.

Bellevue Hospital Medical College.—At the annual meeting of the faculty held on May 7th the following changes were made: The title of the chair held by Dr. Joseph D. Bryant was changed to that of anatomy and operative and clinical surgery; Dr. Bryant to continue his surgical clinic on Saturdays and to give two lectures a week on anatomy and one lecture a week on certain subjects in operative surgery. Dr. George D. Stewart resigned as one of the demonstrators of anatomy and was appointed to give one lecture a week as lecturer ad junc tum on anatomy, under the direction of Professor Bryant. Dr. Stewart was also nominated an assistant visiting surgeon to Bellevue Hospital. Dr. H. M. Silver resigned as demonstrator of anatomy. Dr. John F. Ernhman was appointed professor of practical anatomy and put in charge of the dissecting room. Dr. Winfield Ayers, Dr. William G. Lusk, and Dr. John J. Rothwell were appointed assistant demonstrators of anatomy. Dr. Reginald H. Sayre was appointed lecturer adjunct on orthopaedic surgery. Dr. Austin Flnt, Jr., was elected professor of obstetrics. Dr. William H. Park was appointed instructor in contagious diseases.

The Erie County Hospital.—An open competitive examination of candidates for appointment as house physicians (three vacancies to be filled on June 1st) will be held at the hospital, in Buffalo, on May 28th at 3:30 p. m. Applications should be addressed to Dr. E. J. Gilray, medical superintendent of the hospital.

The Society of Medical Jurisprudence.—The special order at the last regular meeting, on Monday evening, the 13th inst., was a paper by Dr. L. Duncan Bulkley, entitled A Plea for the Legal Control of Syphilis, based upon its Frequency in the Innocent.

The Richmond Academy of Medicine and Surgery.—At the last regular meeting, on Tuesday evening, the 14th inst., the special order was a paper by Dr. T. J. Moore entitled Os- teo-arthritis.
CONCERNING THE AIMS AND METHODS OF HOSPITAL ALUMNI SOCIETIES.*

BY ADOLPH RUPP, M.D.,
PRESCIDENT OF THE CHARITY HOSPITAL ALUMNI SOCIETY, NEW YORK.

If all were true that is said and applauded at the dinners of the different hospital alumni societies, then those who have a suspicion of the imperfection of human institutions would be treated to many manifestations of sentiment that might well puzzle and confound them, although they could fall back on the authority of so sturdy and common-sense a philosopher as Samuel Johnson, who says, "In all sublunary things there is something to be wished, which we must wish in vain."

At those dinners, as you all know, the hospitals are glorified, the hospital men praise themselves and are praised by others, and the alumni societies are lauded on account of the good they do.

Certainly none of us will say that all this buoyant exhilaration is without reasonable foundation. Considering the purity of feeling and the joyous swing of thought and sentiment which prevail on these occasions, all seems well timed and placed.

Long may these annual and biennial reunions at the dinner table continue!

Other places, however, and other times justify and even invite the consideration and discussion of other thoughts and sentiments from other points of view. Then, too, where there is life, problems bearing on the aims and methods of such societies are always presenting themselves for consideration or reconsideration.

This being the last but one meeting of the season, I may be pardoned for bringing to your attention a few facts and fancies concerning our methods in the management of our society, and which I offer only in the way of suggestion. What I shall have to say may have occurred to many of you too. Indeed, some of these problems we have attempted to solve, and with more or less success. A few others have been dismissed by us after hasty and unsatisfactory discussion, as not sufficiently ripe for serious attention.

Article II of the Constitution of The Society of the Alumni of City (Charity) Hospital boldly and baldly tells us that "The object (aims) of this society shall be the advancement of medicine and surgery, and the promotion of social intercourse among its members."

No one will challenge the excellence of such aims, and none can be more consistent with self-respectful modesty. Moreover, these aims are permeated by the spirit of the old text, ever new with vigorous vitality, and therefore always true: "None of us liveth unto himself." Such are our ideals!

What are our methods by means of which we seek and hope to realize them? We have three committees to help us to realize our ideals: (1) A committee to look after the work, etc., which is to advance the science and art of medicine and surgery; (2) a committee to take care of new members; and (3) a committee to take care of all our social arrangements. Besides, we have the usual executive officers, a president and a vice-president, a secretary, and a treasurer.

But all this machinery amounts to only a little at best if the material it works for be inefficient, or lacks a sympathetic and enthusiastic co-operative spirit. Allow me to say a few words concerning the character and personnel of our regular meetings. Too often we see only the same faces and hear only the same voices; and, although all is of first-rate quality, our meetings can not under such circumstances finally become anything else than monotonous. Look at our transactions and I think you will find this to be true.

The men who have shown most interest in our doings by attendance, by the reading of papers, and participation in discussions have been those who left the hospital between the years 1875 and 1885. This is not as it ought to be. The circle is too limited. Why do the men who left the hospital prior to 1875, and those who have left since 1885, manifest so little sympathy for the doings of this society? Perhaps they do not know of our existence as they should. I would therefore suggest that the members of the committee on new members be asked to enlarge their sphere of usefulness. They might, besides passing on the credentials of candidates for membership, look around for candidates, old practitioners as well as the youngest graduates from the hospital. In doing this not altogether easy but pleasant work a number of ideas might suggest themselves to their business faculties which possibly would prove fruitful for the good name of our society and its better operation in realizing the ideals we have made our object.

Another suggestion that I would make refers to the awkward way in which our guests have often been treated. It might be well for our entertainment committee to retire with our guests when our executive sessions are to be of such a nature that absolute secrecy must be the order. We have no right to make our guests feel out of place. They should be made to feel that they are our friends and equals.

And what can the rank and file of the society do in the way of seconding the efforts of the science committee toward advancing the science and art of medicine and surgery, especially so in ways that will make our meetings worth the time of attending them? "Time," says Franklin, "is the stuff that life is made of"—and we medical men should be careful not to waste that which it is our function to rescue and prolong.

An alumns of our hospital, my senior by about ten years, once asked me, "What does your society accomplish?" He also intimated that we could do him no good, that whatever time he might give to our society would be lost, and that his time was gaining in value as he

* Read at the March, 1895, meeting of the Society of the Alumni of Charity Hospital.
was growing older. I could not reply to this argument, because the man, it seemed to me, was as uncomplimentary to himself as to us. He could not appreciate our ideals as we have striven to do, and yet we want and need just such men who know how to appreciate their time. If we can not teach them anything, they can teach us a good deal along many lines of medical science and art. And here excuse me for bringing in a few words on this head from Sir Thomas Browne: "There are infirmities not only of the body but of the soul and fortunes, which do require the merciful hand of our abilities. I can not condemn a man for ignorance, but behold him with as much pity as I do Lazarus. It is no greater charity to clothe his body than appareled the nakedness of his soul. It is an honorable object to see the reasons of other men wear our liversies, and their borrowed understandings do homage to the bounty of ours."

We are practical men, and as such we have interests in common which reflect on us individually. We also have responsibilities to take care of; and we dare not shirk them if we would be live and earnest men and good citizens.

Along these lines our doings here can be a gain to ourselves, and indirectly beneficial to our professional confrères and the public at large.

A German professor and wit of the last century says: "People amuse themselves with uncertainties and call it discussion." There is as much truth in that hit to-day as there was one hundred years ago. But if we take care not to allow inane vanities to run away with our duties our discussions will contain something better than straw-stuffed amusement; and though our reportings, readings, and discussions may not send science forward with leaps and bounds, our doings, we may hope, will help us in keeping our senses open and "free from the mists of prejudice and the paralysis of cant." This free and open sense is on a level with originality and discovery, and only comes after them in importance.

Egyptian civilization shut out new ideas and facts to save its individuality, and died. Greek culture finally assumed a too ardent hastiness for the discussion of something new, forgetting what it had acquired and done in bygone centuries, and the glories of Greece crumbled into forgetfulness and a name, because the Greeks had shut their senses against what had at other times made them great among nations. Our culture individually is only dense and prejudiced if we chase after only what is new and shut our minds against the just claims of what is old. What is true of Egypt and of Greece as great nations is psychologically true for each of us and all collectively. We must work both ways—at the new and at the old. Why were the beneficent virtues of ether left unappllied for centuries after its first discovery? (Discovered 1515 by Valerius Cordus—applied thoroughly and widely after 1845 by Morton, Jackson, and others.) Just because the general medical mind was not prepared to see and accept the powers within its reach.

On the other hand, can we not, even the youngest among us, recall new, loudly commended and recommended therapeutic measures which left many medical men and many lay people in very much the same disappointed plight in which the dog was after he lost his bone because he snapped at its exaggerated reflection in the water? Of course, all the other medical societies have these or similar aims—the advancement and diffusion of our particular branch of science, philosophy, and art. But they lack that bond of fellowship of service which is common to us and our hospital alumni societies, and which makes us a specialized group of men. We all enjoyed the rare opportunities of observation in a large hospital before beginning our careers as private practitioners. Some of us have drifted into the various specialties, some of us are physicians and others are surgeons, and only a few of us are general practitioners.

This being the case—by the judicious management of the science committee, seconded by the ready co-operation of all—we can each of us carry away more from these meetings which keep us in the swim of the great, full stream of medicine than we can from the meetings of any of the other societies, which all have special tendencies, and which are so often in their doings and tendencies like ripples running away from the parent river.

Of course, the other societies have other uses and interests for us all which after a manner bring us in touch with the profession at large.

With one more reminder, coupled with a suggestion, I shall end my speech. By vote, at last month's meeting, the officers and standing committees are its executive committee. The powers conferred are great and may easily be abused. But the powers conferred as they are, properly and fairly worked, will facilitate and expedite all our routine business, and besides heighten and lengthen the social part of our gatherings.

The specific characteristic of the government of our society is "committee government." The offices of president and vice-president are simply and purely honorary. Our president only presides at our meetings—all the rest that he presumes to do he does by the courtesy of the committees and your acquiescence and kindness.

I would therefore suggest, on account of all this, and for the better orientation of all of us, that the names of all officers and the names of all the men serving on the various committees be printed on the reverse side of all the notice cards.

I thank you for your courteous attention and hope that we may all meet again next November.

Phlebotomy of the Hands to Prevent Abortion.—In the Lyon médical for April 28th there is an abstract of an article by Viscaro, which was published in El Siglo Médico, in which the author states that in several cases of threatening abortion he has successfully employed derivative phlebotomy as recommended by the ancient writers. He has practised it on one of the veins of the hand, without drawing more than two ounces of blood. He cites several cases in which he has rapidly obtained the cessation of symptoms of abortion and in which pregnancy has attained its normal term. This treatment, he says, should not be reserved for plethoric women only, although it is contraindicated when the patients are greatly debilitated.
DILLER': AN ATYPICAL CASE OF INSULAR SCLEROSIS.*

By THEODORE DILLER, M.D.,
VISITING PHYSICIAN TO ST. FRANCIS HOSPITAL, PITTSBURGH.

Nearly all authorities agree that insular sclerosis often presents great difficulties in the way of diagnosis. Too much stress is perhaps laid upon the intention tremor as a pathognomonic sign. Certainly in not a few cases this sign is absent.

The following case presents unusual difficulties in diagnosis, inasmuch as this chief symptom is absent, and the patient's condition and history naturally bring up the question of the possibility of the case being one of metallic tremors:

T. C., aged twenty-one years, came to Pittsburgh Free Dispensary, March 19, 1895. Family history negative. Never had any of the diseases of childhood except pertussis. At the age of thirteen years and a half he worked in a chair factory at varnishing. The room was often so filled with fumes that he was compelled to go to the door for fresh air. Whether these were fumes of lead I am unable to make out; but he states that lead was used in this factory, although he did not work in it. He was employed in this place until the age of sixteen, or until a year after the initial appearance of his present trouble. From the age of sixteen to eighteen he worked about a place where nickel and silver plating was done, although he himself did not actually work in these metals. From the age of eighteen until a few weeks ago he worked in a shop where mirrors were backed. Here, again, he did not actually work in the metal (mercury), but was employed at polishing frames.

At the age of fifteen a tremor appeared in the hands. This was apparent upon emotion or attempts at fine movements. It annoyed him especially in writing labels, which constituted part of his duty. About two years ago he noted tremors in his feet. For the past six months he has had a decided tendency to protrude the head forward and to the right in walking. He has gradually grown weaker and emaciated, although he has worked regularly until recently, and even now hopes to resume his occupation.

Examination.—The boy is thin and emaciated. Gait spastic. Walks in a clumsy, shuffling manner, with head protruded forward and to the right. When sitting quietly a very distinct tremor in hands and feet, somewhat coarser than that of paralysis agitans, is noted. Some tremor in the face and tongue during emotion. The tremor in the hands is not increased in picking up a pin, buttoning a coat, carrying a glass of water to the mouth, etc. Both knee-jerks are somewhat exaggerated. Ankle clonus present. Pupils dilated, eyes somewhat protruding, and there is a slight internal squint. No nystagmus. Speech at times somewhat halting. The mental processes are rather slow, and there is apparently some enfeeblement of intellect. There is considerable general loss of strength; no atrophy. Pulse regular, 72.

He states that when he is quiet and alone the tremors are entirely absent, and may remain so for hours at a time.

The visual fields were taken by Dr. Joseph E. Willetts, as shown in the accompanying charts. Dr. Willetts found: L. V. = 2/2; no changes in the fundus. R. V. = 2/4; slight contraction of the arteries; no pallor of the disc, but it is sharply defined.

Remarks.—If this case is regarded as one of insular sclerosis, it must be looked upon as a very atypical one, at least so far as the tremor goes; for Gowers states: * "It is said that in rare instances the movements have been known to continue during rest, but there is some doubt as to the nature of such exceptional cases." When it is remembered that the tremors in this case were present at times during rest, and that what is very generally regarded as the most obtrusive symptom of the disease—viz., the wide, coarse tremor on attempted fine movements—was absent, the difficulties in diagnosis are at once very apparent. I have, however, ventured to diagnosticate the case as one of insular sclerosis from the presence of the other symptoms: viz., the general weakness and enfeebled; the clumsy, shuffling,

spastic gait; the exaggerated reflexes; the presence of ankle clonus; the protrusion of the eyeballs and internal squint; the slight speech affection; and the mental impairment.

Aside from the tremor symptom, it is very evident that the patient is suffering from some serious, chronic, progressive organic disease; and as he presents a tremor, one naturally thinks of the more probable affections of which tremor is a symptom.

The nature of the tremor, the age, and the whole attitude of the patient, at once throw out paralytic dementia and paralysis agitans. Nor does it seem possible that this is a case of Friedreich's ataxia or of Girave's disease. Indeed, the only affection which to my mind arises to present real difficulties in the way of diagnosis is metallic poisoning, and this difficulty is all the greater when we consider that for seven years this boy was in a position to be poisoned by lead, nickel, silver, and mercury. The boy was working in a factory where lead was used, and suffered there from tremors for a year before he left it to take up work in a new place. So, if it is assumed that the tremor is due to metallic poisoning, the initial change must have been set up by lead. From the tremor alone, I know no way of distinguishing it from that produced by lead or mercury. I am disposed to throw out the diagnosis of metallic poisoning, because I have never known instances, nor can I find any in literature where, aside from the tremors, symptoms such as this patient presents were exhibited. On the other hand, leaving out of consideration the tremor, the symptoms the patient presents are very like those frequently observed in disseminated sclerosis.

There is not present now, nor have we a history of colic, palsy of extensor muscles, or blue line along the margin. Assuming this diagnosis of insular sclerosis to be correct, could we in any measure account for the atypical nature of the case by supposing that besides the pathological process of insular sclerosis there is also present as a modifying process some metallic poisoning?

In view of this possibility, and also of some chance that the case may after all be one of metallic tremors, I have deemed it advisable to give the boy for a time small doses of iodide of potassium for the effect it may have in eliminating any of these poisons which may be present in his system; and as I have no knowledge of any drugs which have any real curative effect in disseminated sclerosis, this course in therapeutic seems to me the best under the circumstances. Hyoscyamine has in this case (as it will in most cases of tremors of any sort) notably controlled them.

WESTINGHOUSE BUILDING.

The Treatment of Headache.—In the Lyon médical for May 5th there is an abstract of an article by Dr. Mollis, which was published in the Union pharmaceutique. The author finds that it is possible to stop the tendency to fresh attacks of headache by the use of sodium salicylate. Every evening, and also in the intervals between the attacks, fifteen grains of this drug should be given in a cup of black coffee. Its employment is to be more or less prolonged according to circumstances. The author does not hesitate to use morphine subcutaneously in cases where the pain is too violent to yield to the employment of antipyrine, sodium salicylate, etc.

THE DIAGNOSIS OF CHRONIC JOINT DISEASE.*

By W. R. TOWNSEND, A.M., M.D.

Is the subdivision of medicine into specialties, chronic joint diseases are usually referred to the orthopedic surgeon for treatment, but the early diagnosis of these affections has to be made by the general practitioner. He first sees the patient, and either correctly interprets the symptoms of beginning trouble, or, after a more or less careful examination, decides that the condition is due to a sprain or to rheumatism, or perhaps detects nothing abnormal, only to learn later, in many cases, that he has made a serious error.

Many a practitioner, when called to such a case, will admit his lack of knowledge and at once call in a consultant, who can correctly interpret the signs present. This, while preferable to committing serious errors, should rarely be necessary, for all practitioners should be able to make the diagnosis, at least in the simpler cases. Obscure and difficult types will require much thought and large experience to correctly interpret, but they are not often seen.

Errors are usually due not so much to ignorance as to a failure to thoroughly examine the patient. Many, however, lack the necessary knowledge of how to examine and bring out the symptoms, and the object of this paper is to refer to the principal symptoms of chronic joint disease and to show how the examination should be made to detect their presence or absence.

In speaking of chronic joint disease I refer to those cases of arthritis or osteitis, chronic in nature, due to tuberculosis or trau-matism, beginning either in the joint structures or in the bone, which are mostly seen in the first two decades of life. In examining a patient with suspected joint trouble our first step is to obtain a careful and accurate history. This is not always an easy matter, and too much reliance must not be placed on statements made until a very close cross-examination proves that the parent or patient is an accurate observer; for chronic joint disease comes on, as a rule, insidiously, and the first symptoms are apt to be overlooked, and a serious exacerbation due to a traumatism will be assigned as the cause and beginning of the disease when it is not. But histories have their value, and should be weighed with the symptoms in making a diagnosis.

The most constant and characteristic symptoms of chronic joint disease are reflex muscular spasm, limitation of joint motion, deformity, atrophy, and pain. The presence of these symptoms, with the history, will enable us to make the diagnosis.

The instruments used to aid us in the examinations are few and very simple. An ordinary tape measure is necessary to determine any alteration in the length or in the circumference of a limb, and also either an increase or decrease in the size of an articulation. The steel tape, while it may be more accurate, is not as convenient as the ordi-

* Read before the Society of Alumni of Bellevue Hospital, April 3, 1896.
nary tape; it is too stiff and unyielding, and our preference is for the cheaper and simpler one.

The only other instrument needed is a goniometer. This is used to measure the amount of motion of the joint. It consists of a half circle, with the degrees marked upon it from zero to one hundred and eighty. There are two arms to it, one fixed, the other movable. The fixed arm has attached to it the graduated arc. The movable arm has its centre of motion opposite the ninety-degree point, and when placed at zero and one hundred and eighty degrees is exactly parallel with the fixed arm.

To measure the amount of motion of any joint, we place the instrument opposite it, the joint centre of motion being opposite the centre of motion of the movable arm, and by having the two arms correspond with the long axis of the bones entering into the articulation any movement of the joint will show us in degrees the amount. This gives an accurate measurement, and may enable us to detect slight limitations which might otherwise be overlooked.

The most important symptom in chronic joint disease, as was first prominently pointed out by Shaffer, is reflex muscular spasm. It is among the earliest to appear, and the one upon which we rely the most to make a diagnosis. It is an involuntary muscular protection of the articulation; it precedes the limp, and may really be said to cause it, for, disease being present, reflex spasm causes a limitation of motion in one or more directions, and this causes a disturbance in the rhythm of the gait, and a limp follows necessarily. This muscular spasm may be very slight and only noticeable at the extremes of motion, and there may be no deformity as a result; or it may be so great as to lock the joint, and this usually occasions deformity of a marked degree. Spasm is present by day and by night, does not yield to sleep, but completely disappears under anaesthesia, hence the uselessness of giving an anesthetic to determine whether or not there is beginning joint disease.

To this condition of spasm we may in some cases attribute the pain in the articulation, as it tends to bring in contact the diseased surfaces, and this may be the cause of the night cries.

These night cries are quite characteristic of chronic joint disease, and while their absence is not proof positive that disease does not exist, yet their presence is very suggestive of it. They are more frequently found in disease of the larger articulations than when the smaller are affected. The night cry of spinal disease is more apt to be dull in character, rather a moan than a sharp cry, which latter prevails in hip and knee disease. The position taken by Valette, "that there can be no hip disease if the motions of the joint are perfect," is also true of other joints. The reflex muscular spasm, when once present, remains until a cure is effected, and this is important. The limp may apparently disappear, yet, if true joint disease exists, examination will show a limitation of the normal movements, although it may be very slight, or may only be clearly brought out when the child is fatigued. Of course, it also follows from this that we may make the diagnosis before lameness occurs. Careful and constant examination of normal and diseased joints will enable any practitioner to acquire the tactus eruditus, and to distinguish reflex muscular spasm when present.

As a result of the joints and the muscles about them being supplied by the same nerves, atrophy is another early symptom of value. Brown Séguard years ago showed that nerve irritation alone was capable of determining rapid and early atrophy of the muscles with a decrease or disappearance of the faradie contractility. This atrophy is not necessarily due to a neuritis, but rather to trophic changes and comes before disease of the limb could cause it, although the latter is a potent factor later on in the disease.

This atrophy usually affects muscles on both sides of a joint, but principally those whose nerve supply is the same as the joint. The atrophy also causes changes in the contour of the parts, and in many cases an apparent increase in size of an articulation is simply due to atrophy of the parts near by. Pain may or may not be a symptom of chronic joint disease; it is very unreliable, and may not be felt at all in the diseased articulation, but at the terminations of some of the nerves sending filaments to the joints, as the pain of Pott's disease often felt in or about the stomach, and the pain of hip disease felt at the knee. Some patients have joint disease with abscesses and serious complications and yet never have pain, while in others it is a most prominent symptom. Joint tenderness or pain on pressure also varies greatly. The absence of pain is not of great value, but its presence with other symptoms is. The deformity in joint disease is due usually to the muscular spasm in early stages, later to joint changes; and with this brief description of the principal symptoms I will refer the reader to the various text-books on surgery for description of the particular symptoms in each joint, and now give a short account of the normal movements of the different joints, and how to examine them to determine the presence or absence of reflex muscular spasm and limitation of motion, of atrophy, and pain.

In the first place, it is absolutely necessary in the examination of any joint that the clothing be removed to a sufficient amount to permit of free inspection of the joint, and of the corresponding one of the opposite side. In the case of young children no difficulty is experienced, and there will be none in those of more mature years if the necessity for the procedure is explained to the patient.

Disease of the Spine.—To determine the presence or absence of reflex muscular spasm in spinal disease it is necessary to have the patient stand before us so that the
entire back can be clearly seen. If the disease affects the cervical region, the muscles in and about the neck, both posteriorly and laterally, will be tense in a state of spasm and prevent free motion of the head. The head may be inclined backward, forward, or to one side, and so held.

Systematic and methodical examination should be made here as also in all other joints, for only by such methods shall we be sure to overlook nothing of importance. The patient standing erect, note should be made of the contour of the spine, whether the normal curves are present, and whether there are any lateral, posterior, or anterior deviations. The movements of the head should then be tested, whether the patient complains of symptoms especially referable to that region or not. First, cause the head to be lowered so that the chin may approximate the sternum, then cause it to be raised and bent backward so that the occipital portion approximates the spine. Then ascertain the amount of lateral motion by causing it to be rotated so that the chin first approaches one shoulder, then the other. The patient having done these motions alone, grasp the head in your hand firmly but gently, and passive motion will give you the limits, if any, and enable you to detect the presence or absence of muscular spasm. The back itself should then be tested by causing the patient to bend forward, backward, and to either side, and comparing the amount of motion with the motions of the normal spine. The movements of the lumbar and lumbo-sacral spines can not be well tested with the patient standing, so we examine for the presence or absence of spasm in these parts by causing the individual to lie on the face on a hard couch or table, and by raising the lower extremities with the hands we can detect any limitation of motion.

As we have no other joint in the same individual to compare these movements with, careful examination should be made of normal spines in patients of different ages to acquaint ourselves with the normal limits. Of course these vary greatly; the stout and the aged are far less supple than the thin and the young, and acrobats and gymnasts can bend far beyond the normal average; but a little practice will tell whether the inability to bend the spine is due to reflex muscular spasm or not. In some instances the spinal muscles will stand out prominently, being firmly contracted; but this is not always the case. When spasm exists in the cervical region alone, the lower dorsal and lumbar regions may be freely movable, and spasm of the lumbar region may not interfere with the motions of the head, but disease of the dorsal and lumbar regions is usually accompanied by a stiffness of the entire spine. It moves as one long bone, not as a number of small ones. In the normal spine the hips can be raised easily to form an angle with the vertebral column of thirty or forty degrees, and the motions laterally are very free, and any limitation, especially if accompanied by pain, should cause a careful examination to be made to see if any other symptoms of spinal disease are present.

No motions or tests should be made, except with the greatest possible care, to elicit pain in the vertebrae; violent jarring of the head or severe bending of the spine may produce serious injury, and is never necessary to make the diagnosis.

Atrophy in spinal disease is difficult to measure, but may exist; it is of less importance in these cases than in disease of other joints.

The Shoulder.—In examining the shoulder and other joints besides the spine we have the benefit of another articulation of the opposite side for comparison, for there are practically no cases on record where similar joints of both sides of the body have been affected with chronic joint disease beginning simultaneously, although disease in one articulation may very rapidly follow disease in another.

The motions of the shoulder joint are flexion, extension, abduction, and adduction; and the combination of these in quick succession produces circumduction. In addition to these we have rotation, which is the movement round a vertical axis through the extremities of the humerus from the point of the head to the inner condyle, and this may be forward or backward.

The movements of the shoulder are very free, and in chronic joint disease always more or less limited, usually abduction being most markedly so. Normally the arm can be abducted to ninety degrees by the deltoid, and then raised even more than ninety degrees further by the trapezii and others.

Each motion should be carefully gone over and tested with the similar motion of the other shoulder, and spasm and limitation of motion will easily be detected. The amount on each side should be measured for purposes of comparison. Here, as in other joints, it is best to examine the normal joint first, as it often enables us to acquire the confidence of the patient, especially in children. The circumferences of the parts in and about the shoulder should be measured to determine the presence or absence of atrophy, and no tests made to elicit pain.

The Elbow.—The elbow being a hinge joint, flexion and extension are the only movements which can take place. These movements are oblique, the forearm being inclined inward in flexion and outward in extension. Flexion and extension are limited by contact of the coronoid and olecranon processes of the ulna with their corresponding fossa in the humerus. The limit of extension is reached when the ulna and humerus are nearly in a straight line or at about a hundred and seventy-five degrees; and flexion can be carried up to about thirty-five degrees, and is not limited by the coming in contact of the soft parts of the forearm and arm, but upon the proportion which the length of the olecranon and coronoid processes bear to the depth of the olecranon and coronoid fossae. Any limitation in these motions accompanied by spasm, atrophy of parts below and above, and pain, together with the history, will enable us to make the diagnosis.

The Hip.—This is the joint we are most often called upon to examine; and to properly examine it, the patient should lie flat on the back on a hard couch or table, so that the spine can be made to touch the table and any tilting of the pelvis can be noted.

The normal motions are flexion, extension, abduction, adduction, rotation, and circumduction, but the latter may
be left out in tests for limitation of motion. Extension beyond a hundred and eighty degrees is often spoken of as hyperextension, thus giving us seven motions.

The movements should be carefully examined and in regular order. The limb should be grasped firmly, and each motion carried to the full limit, or until spasm is elicited and the motion checked.

In well-marked cases of hip disease all movements are restricted, but in beginning disease only a few may show this restriction, and in such cases the greatest attention is to be paid to interference with abduction, superextension, and external rotation. Interference with extension alone is more apt to be due to spinal disease as a result of psosas and iliacus contraction than to hip disease.

The normal limits of the various movements at the hip vary considerably. Flexion is checked at about ninety degrees by the hamstring tendons if the knee is straight; but if the knee is bent it can be carried from forty to sixty degrees further, being then limited by the contact of the soft parts of the thigh against the anterior superior spine and abdomen. But the normal limits are greatly exceeded by many gymnasts and high kickers. The limitation from a straight knee should always be borne in mind, for the error is often committed that flexion of the thigh is limited when no such limitation really exists. Where knee disease is present, the thigh must be grasped above the knee and care taken not to make motion at the knee at the same time we make motions at the hip. Extension should be tested with the patient lying on the back, and such position is limited to a hundred and eighty degrees. To test for superextension, place the patient on the face, grasp the thigh, and note the distance the knee can be raised from the table. Usually the amount of superextension is about forty degrees. This motion is limited by the iliopsoas ligament.

Abduction and outward rotation are possible in any position of the leg. Abduction may be carried to ninety degrees, but the average is about forty degrees; and when abducting the thigh it is well to steady the pelvis with the other hand so as to note the least spasm, which at once causes the pelvis to tilt.

Adduction and inward rotation should be tested for both with the thigh extended and flexed. When the thigh is extended the range of motion is much less than when flexed, because of contact with the opposite limb. It averages about thirty degrees. Rotation is best brought about by having the patient on the back and rolling the thigh under the hand.

Too much attention is usually paid to the division of hip disease into stages, with descriptions of the different deformities in each stage. Determine the presence or absence of reflex spasm, the presence or absence of atrophy of the thigh, the night cry, and the presence or absence of pain in the articulation, get the history, and the diagnosis can be made; and then the position of the limb should be noted, whether ab ducted or adducted, flexed, rotated in or out. That in the first stage abduction and apparent lengthening are the rule, in the next adduction and apparent shortening, in the later stages flexion, adduction, and real shortening, are facts which will necessarily follow when the disease is more closely studied. The position of the thigh and the presence or absence of atrophy will determine the shape of the nates, and the position of the fold of the buttock the gluteal crease.

In early examinations it is not advisable to use Thomas's test to determine the amount of flexion, as it may increase intra-articular pressure. This test is made by flexing the sound thigh on the abdomen and holding it there by the patient's hand placed in the popliteal space, then bending down the diseased limb as far as possible. In testing for pain, never use force; never jam the head of the femur against the acetabulum by knocking on the heel.

The Knee.—In the knee the motions are extension and flexion, and when the limb is flexed a slight amount of pronation and supination. The movements, though, are much more complicated than at the elbow, as it is not a true hinge joint.

Remembering the fact that the points of contact of the articular surfaces shift, we see how the subluxation deformity so easily occurs when the hamstrings are firmly contracted by muscular spasm.

The limitations of normal motion are in extension when the tibia and femur are in a straight line. The patella is usually freely movable, and all the ligaments of the joint are on the stretch save the ligamentum patellae and the front of the capsule. The motion is checked by the cruciate and lateral ligaments.

Complete extension is always interfered with in chronic joint disease, and the inability to bring the knee perfectly straight is an important symptom. Flexion is limited by the contact of the soft parts of the calf and the posterior surface of the thigh. Starting with the leg fully extended at zero, it is permissible to the extent of a hundred and thirty to a hundred and sixty degrees, according to the fleshiness of the individual. Its limits can be easily determined in a diseased joint by comparing it with the sound joint.

Pronation and supination are limited even in the slightest cases. The amount of rotation in the normal joint when the knee is flexed forty degrees varies, but is about thirty degrees.

Atrophy is usually present both in the lower part of the thigh and in the calf.

Pain on pressure may be felt at this articulation, and is usually referred to the inner side of the joint, where the capsule is the thinnest and the bone nearest the surface.

The Wrist.—The normal movements of this joint are flexion, extension, abduction, and adduction, and the combination of circumduction. Comparison of the two sides will show any differences, and spasm can be easily made out.

The Ankle.—This joint, being of the true hinge variety, permits only flexion and extension, but a very slight lateral movement is permitted when the foot is in extreme extension. Flexion may be carried to about forty degrees, and extension usually not over ten or fifteen degrees.

Movements of the smaller joints need not be discussed,
THE PRESERVATION OF THE PERINEUM.
A NEW METHOD.

By D. B. McCARTIE, M. D.,
NEWARK, N. J.

There are many methods recommended in order to preserve intact the lower section of the vaginal outlet, which for the sake of brevity and description is called the perineum. If we take the vagina as a canal, the perineum may be said to inclose the posterior segment of its lower outlet, and also to fill in this outlet by a kind of elastic plug which reaches from an angle on the posterior wall and slopes downward to meet the skin at the margin of the posterior vulvar junction.

To preserve the middle section, but more particularly the marginal band, of this tissue during the passage of the fetal head through it, becomes a specific duty for the physician as well as a great benefit for the patient. It is, indeed, the most important part of the physician’s work in the end of the second part of a labor to direct his attention to the preservation of this tissue. He can do very little to help the uterine force, but he can do much to control its action on the lower genital segment by preventing the child’s head from coming in contact too violently or too soon with a tissue which may not be prepared to allow the passage of the fetal head.

The old plan to preserve this tissue from laceration was to “support the perineum.” This meant that the hand should be placed flatly against the bulging surface of the perineum so as to prevent it bulging too much. It has been found that this method, like any other obstruction to uterine force, only increases the uterine contractions, and may even retard the labor, since the pressure acts too directly in the axis of the propelling force. Moreover, by this means the center of the perineum is mostly supported, and this is the part that least needs support, while the marginal edge is as much liable to tear as ever. For many reasons this procedure has passed out of use, and other and better methods are employed.

The other methods entail a double procedure: First, they aim at preventing the too rapid advance of the head; and, secondly, they make use of an artificial propelling force by which the head is pressed toward the outlet under the pubic arch. The object of the various methods employed must necessarily contend against the too rapid and too spasmodic force from behind, since it is this force that ruptures the perineum; but the second part of the procedure—namely, the pushing forward of the head under the pubic arch—seems worthy of some modifications, if, indeed, we should attempt to use any force at all in this direction, with the view of pushing the fetal head through the vulvar outlet.

This paper deals, therefore, mostly with the second part of the rule laid down in every text-book as to the best means of saving the perineum from laceration, and also with the best mode of applying a counteracting force so as to prevent the too rapid advance of the fetal head. The pushing forward of the head after it reaches the perineal floor is, as a rule, uncalled for, and against the use of Nature, except in special cases. This method of itself is sufficient to cause laceration, which is the very thing we are trying to prevent.

If it is necessary to deliver the head quickly—and this must be a rare condition—it can be pressed forward from behind. This is especially easy in a large multipara, when the rupture of the perineum is scarcely possible; but if the head be artificially pressed forward in a primipara where the perineum is at stake, it often helps, I believe, to lacerate the parts we strenuously wish to preserve. There is a wonderful aptitude on the part of the physician to push the child’s head forward and so terminate the labor, as there is a natural tendency on the part of the patient to be delivered from pain.

Before describing the method I intend to propose as a safe and natural one, by which the fetal head can be aided in its exit from the vulva with the least risk of rupture, it may be necessary to mention a few of the most common methods in use at the present time.

One method is as follows:

“The index finger of the right hand may be placed on the thin edge of the perineum so as to note its tension, while the tips of the remaining fingers placed on the occiput check its advance when tension becomes too great. At the same time the left hand is spread out flat behind the perineum, so that the index finger and thumb press on the head a little in front of the sacro-sciatic ligaments on each side and direct it forward, without exercising any pressure on the sensitive central portion of the perineum where the strain is greatest. Thus both hands act together in checking advance when necessary, while the left hand keeps the head forward against the pubic arch. The patient is not to hold her breath, and chloroform should be used if she loses her self-control.

“There is another mode of directing the head forward besides that of spreading out the thumb and fingers in front of the sacro-sciatic ligaments—namely, to pass the thumb or fingers through the dilated anns into the rectum and press on the head through the recto-vaginal septum. This is mechanically very effective; on the whole, it is not so desirable a plan as the other.” *

The percentage of laceration of the perineum is put down by Ohlhausen as 21 per cent. in primipara and 4 7 per cent. in multipara.

Other measures adopted to save the perineum from rupture are Hohli’s, which consists of applying the thumb anteriorly to the occiput, and the index and middle fingers posteriorly upon that portion of the head which lies nearest to the commissure. The unconstrained position of the hand enables the operator to exercise effective pressure in

the direction of the vagina, while the posterior fingers favor the rotation of the head under the pubic arch.

Rutten's method consists in lifting the head upward and forward through the vulva between the pains by pressure made with the tips of the fingers upon the perineum, behind the anus, close to the extremity of the coccyx.

All the various methods employed and described have in common two indications: one being to retard the passage of the head, and the other to press the head forward behind. The first condition is a necessitous one, since the rupture occurs because the head passes too spasmodically through a canal that is not sufficiently dilated; but the second part of the procedure seems more liable to rupture than to preserve the perineum. For this I shall give the reasons later.

One of the latest methods which has found warm advocates is rectal expression. "This manoeuvre consists in passing two fingers into the rectum toward the close of the second stage and hooking them into the mouth or under the chin of the child through the thin recto-vaginal septum. By pressing the face forward and upward the normal rotation of the head beneath the pubic arch can be effected, and delivery can be accomplished between the pains at the will of the operator."

A recent author recommends hooking two fingers into the anus and drawing the perineum forward during a pain, to remove the strain from the thinned border of the vulva and to promote the elasticity of the tissues.

Fasbender places the patient upon the left side, then standing behind her, he seizes the head between the index and middle fingers of the right hand applied to the occiput, and the thumb thrust as far into the rectum as possible. By this manoeuvre the head is held under complete control, the rectal wall hardly affecting the grasp in any appreciable manner. During a pain the progression and extension of the head are readily prevented. During the interval between the pains, by pressure with the thumb through the rectum and the posterior portion of the perineum, the head can be pressed forward and outward at the will of the operator.

The various methods described deal very little with the position of the head in its passage through the vulva; in fact, the authors of these methods all assert that the head, in one manner or another, should be helped through the vulvar outlet by means of extension. The idea of extension as the natural process of birth is evidently adopted on account of the slight curve at the lower end of the genital canal. The curve of the canal is somewhat in a forward direction, but if the perineum or soft parts were removed, the axis of the canal from above downward would look somewhat backward. The curve in the coccygeal bones also adds to the idea of a forward curve, but these parts are almost straight when the pressure of the head dilates them. The head of the child is pressed directly downward on the perineum, the resistance of which, being greatest behind, pushes the occiput forward, so that when the head is freed from the outlet the elastic perineum, still acting on the frontal region, presses the occiput toward the abdomen of the mother.

But it does not follow that this mode of extension of the head is in progress all the time before the head is born. On the other hand, flexion is naturally maintained; the elasticity of the perineum, acting from behind, is counteracted by the outer rigid bony parts of the genital canal while the head is descending. When the forehead meets the perineal floor extreme flexion occurs, thereby giving the occiput the best chance of slipping out of the genital canal and passing under the pubic arch. As a consequence of this we see the occiput born long before the forehead.

When, therefore, the occiput is born, the pressure of the elastic perineum from behind pushes the base of the occipital bone under the pubic arch, and thereby some extension is caused.

This is usually the time when the action of the physician is called for, and, according to the rules already referred to, his duty then is to cause the head to rotate or extend itself forward and sweep over the perineal floor.

I would strongly advocate the opposite of this, which means that the act of extension is uncalled for, and that the head should not be pressed forward, since this very action tends to rupture the soft parts. On the other hand, when the resistance of the bony parts of the pelvis is removed by descent and exit of the occipital region of the head, the physician should substitute a force for the natural one, to counteract the elasticity of the perineum and keep the head flexed. There can be no doubt that it is extension of the head that lacerates the perineum in most cases after the occiput has slipped under the pubic arch. The flexion of the head can be maintained in a very simple and easy manner, as follows:

The patient should be on her left side to get the best results. The head is to be kept flexed even while in the genital canal, though this is not an absolute necessity; but after the occiput has reached the outlet and we can easily grasp it, it is best even at that early stage to begin flexing the head, since this helps to allow the occiput to slip from under the pubic arch earlier than it otherwise would, and also helps to dilate the perineum by keeping the forehead region rigidly compressed against it. When a part of the occipital region is born it should be grasped by the fingers in front by the right hand (i.e., the fingers near the mons Veneris of the mother), and the thumb behind on some portion of the parietal bone. By this method the head can be kept thoroughly flexed in a most easy and satisfactory manner. The uterine force can be easily counteracted, and the extreme efforts of the patient are easily controlled, because, the head being thoroughly flexed, the force is controlled in the direct axis of the uterus; but, more important than this, the elasticity of the perineum is counteracted, and extension or rotation over its floor is prevented. The two forces, uterine and perineal, are directed more into a downward movement of flexion, and not in a forward one of extension.

The reasons for the adoption of this procedure are as follows:

1. The smallest diameter, the suboccipito-bregmatic (three inches and three quarters), is the first part to meet the vulvar outlet, and besides being the smallest it is also
the longest, and tapers smoothly and gradually toward its thickest diameter. It therefore forms a natural dilating plug, and if kept thoroughly flexed gives the soft parts the best chance of allowing it to pass without rupturing them.

2. If the head is kept thoroughly flexed the forehead is pressed against the resisting part of the perineaum behind, which tends to press the occiput forward and downward, but mostly to guide the uterine force in a downward direction. But if the forehead is pressed forward by any of the methods employed, the force of the perineaum, which would naturally direct the head in a downward direction, presses it almost directly outward, and tends to lacerate the soft parts by the act of extension. But what is exceedingly more dangerous to the integrity of the perineaum, namely, an exchange of a larger diameter of the head for a smaller one, occurs. The occipito-frontal diameter of four inches and a half is exchanged for the suboccipito-bregmatic of three inches and three quarters. This immense gain of three quarters of an inch at such a crucial time is not likely to act as a preservative agent in protecting the soft parts, and especially when we consider that the part then presenting at the lower region of the perineaum, and which will escape through the perinaeum, is not an elongated, dilating, and flexible plug, as the occipital region, but a hard, semifrontal, rigid, and bossy plug, as the front part of the cranium.

3. Extension of the head does not naturally occur to any degree worth speaking of before the entire head is born. In fact, the genital canal when dilated must be almost straight, except for the slight curve of the perineaum. The head turns up when it is born (extension) because the suboccipital region is first born, and being no longer opposed by the rigid structures of the pelvis, the perineaum forces it toward the abdomen of the mother. After it slips under the pubic arch it remains pushed up there by the pressure of the perineaum on the frontal and postfrontal regions. When this pressure is removed as the forehead is born, the forehead is released from pressure and the head naturally falls downward.

4. The occipital region, being born first, slips under the pubic arch. If the occipital region is then seized by the fingers, the thumb being on the postfrontal region in some site over the parietal bones, thorough flexion can easily be maintained. The chin can be pressed on the chest, the forehead can be kept well backward against the posterior aspect of the perineaum, and as a consequence of this the perineaum directs the head somewhat outward and downward. The physician retains the flexed condition with one hand, so that the smallest diameter is always presented with the least fear of rupturing the soft tissues.

5. Extension of the head over the perineaum as it passes forward is not the natural process of birth. It is a convenient way to precipitate the birth of the head, but it is premature and unnecessary when the perineaum is rigid and liable to rupture. The long arm of the lever maintains the flexed position until the last unless interfered with. The sloping elastic perineaum also tends to preserve flexion while the head is passing it, and it is when the head passes beyond control of the perineaum that extension toward the abdomen of the mother takes place.

The amount of extension that takes place then is very little. The occiput being free on account of the slope of the neck, the pressure of the perineaum from behind pushes the head in an upward direction. This occurs on account of the sloping formation of the occipital bone and the pressure from behind; but it does not follow that extension of the forehead occurs in the genital canal. Flexion is maintained by the perineaum as long as the occiput was opposed by the rigid walls of the pelvis.

The idea that active extension is going on in the vagina is mostly held because the head is thrown into marked extension when the occiput is liberated, but this naturally follows because the occiput becomes free to move after the resistance of the pelvic bones is removed and the perineaum still continues to act. This is, then, the peculiar time for active work on the part of the physician who wants to save the soft parts from rupture. After the occiput is born the perineaum is mostly unopposed, and the action of its continued force is to extend the head slightly, or, in other words, to help to sweep the forehead over the perineal floor. This endeavor to extend the head should be controlled by the physician, since extension means a larger diameter with the bossy forehead and sharp margins of the eyebrows opposed to the soft parts of the margin of the perineaum.

The occiput in its first passage through the vulva never tears it. It gradually thins and stretches the soft tissues until it slips under the pubic arch. Then occurs the danger that some extension will take place and the vertex and frontal regions sweep over the perineaum. After the largest diameter is through the thinned-out perineaum is further subjected to strain, when it peels over the lower frontal and face regions until the head is born.

By the method I suggest, therefore, extreme flexion is to be maintained from first to last. The fingers on the head should try to maintain flexion and resist extension even before the occiput is born. This helps to free the occiput early, and it slips under the pubic arch. Then the fingers of the right hand grasp it firmly, while the thumb of the same hand is placed over the parietal region and flexion rigidly maintained. By holding the head in such a fashion the strongest pains are easily controlled, and the head, at the judgment of the physician, can be let out half an inch or an inch, according as he desires. This desire will be actuated by looking at the margin of the perineaum and noticing how much the parietal bones stretch it during a pain. If the thinned-out margin of the perineaum grows too thin, becomes white and glistening, the eye appreciates the danger and the hand counteracts the force of the uterus by maintaining flexion. It will be found that the strongest pains can be readily controlled with one hand by this means.

If the perineaum is very rigid it can be softened during the interval between the pains by slightly extending the forehead and pressing it back into extreme flexion again. Of course this manoeuvre is to be repeated.

If this method is employed, the danger to the perineaum
is greatest when the bony forehead and postfrontal region is about to pass, and this is mostly so because it passes quickly and the physician is desirous to have the head born. It is difficult to await this stage; but there is no hurry as regards the safety of the child, so the physician must judge very accurately how much he will allow the next pain to propel the head. If a slight tear occurs he had better keep the head back for several pains, and adopt the usual precautions by telling the patient not to strain too much or hold her breath, but, above all, he should avoid any degree of extension of the head. I believe most perineums are ruptured by extension of the head in the anxiety to terminate labor, and where no assistance is at hand to check the too vigorous endeavors of the patient.

There is also another reason why extreme flexion should be maintained. If any degree of extension takes place, the uterus, acting directly from the back to the head, forces the vertex against the lowest and thinnest part of the perineum, and this reason by itself would be sufficient to rupture so delicate a tissue; but where flexion is maintained the uterine force is directed through the forehead against the sloping wall of the perineum, which takes the force off the lower part of the perineum and also acts indirectly in pushing the occipital region toward the vulvar outlet. But if this indirect force is removed by extending the head and thereby removing the forehead from the sloping wall of the perineum, the entire action of the uterus is directed downward on the lowest and thinnest part of the perineum, which it bulges and may tear centrally; besides, it loses the forward expelling force it gets when the forehead is well pressed against the sloping wall of the perineum behind.

The patient should lie on her left side if the physician wishes to gain control over the perineal region. With the patient on her back it is impossible to control the uterine force in a satisfactory manner. The situation is very unsatisfactory where active manipulation is required. If the patient can not lie in the lateral position the above indications can still be fulfilled. The head can be kept thoroughly flexed with the right hand, and the physician should try and watch the lower margin of the vulvar outlet.

The methods in vogue strive to "shell out," as it were, the child's head from the genital canal. This might be well done in a multipara, where the perineum is loose and delay unnecessary; but in a first birth the manipulation from behind, and the consequent substituting a larger occipito-frontal for a much smaller and tapering suboccipitobregmatic, is, to say the least, an unnecessary procedure. The small vulva of a primipara can not be forced open by any such method. Extension adds to the gravity of the situation. Flexion gives most satisfactory results. The perineum will not tear if time be taken and judgment used as to when the physician should allow the largest diameter of the presenting part to pass through the thinned and shining surface of the vulvar outlet. Much caution is required in taking the latter step, since it is very easy to mistake the amount of the facial head that is still to pass through, and an ardent wish for delivery on the part of the patient and the physician is present. The guide to this step is almost entirely the thinly stretched margin of the vulva.

It does not matter how much of the head is born if the vulvar margin is too tightly stretched. It is better, in order to avoid laceration, to return the whole head into the vagina and allow it to advance very little at the next pain.

If thorough flexion is kept up and no force used from behind—in fact nothing but the regulating force of the right hand in the position recommended—it will be found that rupture of the perineum will be a rare event.

106 BELLEVILLE AVENUE.

ON THE THYREOID THERAPY: ITS HISTORY AND ITS USE IN INTERNAL MEDICINE.*

By S. J. MELTZER, M. D.

It is just a year now since I permitted myself to offer to you an extensive account of myxœdema.† For my attempt to speak again to you on nearly the same subject I have to shift the responsibility to our worthy president, who arranged for our meeting to-night a discussion of the therapeutic value of the thyreoid, and assigned to me the history of this new therapeutic agent and its application within the domain of internal medicine.

I have to confess, however, that I am rather glad of the opportunity to present to you once more the history of the specific treatment of myxœdema for the purpose of separating it from the doubtful company in which we are meeting it lately. I shall not speak of the advertised thyreoidine together with ovarine, cardine, etc. I have in mind rather those serious, scientific circles where the tendency lately became prevalent to bring together heterogeneous elements of treatment under the one head of the therapeutics of animal extracts. I remind you of the paper read by Fürbringer last winter at a meeting of the Society for Internal Medicine in Berlin. The title of the paper reads: On the Modern Treatment of Diseases with Fluids of Animal Tissue.‡ These fluids are counted up in parenthesis as follows: testicular, thyreoid, pancreatic, nerve, heart, and kidney juice (Hoden-, Schildrüsen-, Pancreas-, Nerven-, Herz- und Nierenfltissigkeit). In the discussion following this paper Goldscheider§ reported that in a series of observations made by him in Leyden's clinic with several of the animal extracts it was established that none of these fluids had proved to be efficacious in the diseases for which they were employed. The tested animal tissues were pancreases for diabetes, thyreoid for myxœdema, bone marrow for pernicious anaemia, spleen for leucæmia, etc. Goldscheider considers this line of thera-

† S. J. Melzer. Ueber Myxœdema. New Yorker medicinische Monatschrift, April, 1894.
peuties as a dangerous departure within internal medicine. I shall furthermore refer you to the recent paper of Henry Hun,* On the Use and Abuse of Animal Extracts. Though an enthusiastic admirer of the therapeutic properties of the thyroid, he does not hesitate to treat it under the same head with Hammond’s products. These few instances will suffice to prove the prevalence at present of a tendency to classify the thyroid as belonging to the newly formed group of the so-called animal extracts.

The association of the thyroid with the doubtful company is due not only to its being an animal tissue—there is rather a more conclusive argument for uniting the specific remedy for myxœdema even with the worst elements of the animal extracts. Myxœdema is caused by the absence or diseased condition of the thyroid in the animal body. The feeding of the animal with thyroid removers the myxœdematous state. Here, then, we see how the function of an absent or diseased organ can be supplemented by feeding with this organ of another animal. And this and nothing else is the idea upon which the treatment with cardine, ovarine, etc., is based. Furthermore, the historical sequence of events seems rather to justify even a closer union between the treatment of myxœdema with the thyroid and the medicinal use of testiculine, cardine, etc. As you know, the idea of the animal extracts in its present form is to be traced to the proposition of Brown-Séquard to treat impotence with testicular juice. Two years later Paul and Babes suggested the treatment of the diseases of the brain with cerebrine, and the diseases of the kidney with nephrine, etc. This suggestion was simply an extension of the fundamental idea underlying the testicular therapy. And then followed the communication of Murray of the successful treatment of myxœdema with thyroid, a method which at about the same time with Murray was proposed also by Brown-Séquard (with d’Arsonval). It is therefore only natural for those who do not know the real history of myxœdema and its treatment to assume that the thyroid therapy also is simply a consequence of the old notion that the reduced function of a diseased organ can be improved by eating the identical organ of an animal. The notion is old, for according to Pliny the Greeks and Romans ate the testicle of the donkey for the sake of remedying impotence. Therefore we see how those who distrust the value of the animal extracts believe themselves justified in casting a slur upon the thyroid treatment also. On the occasion of the demonstration of an improved case of myxœdema by Professor Mosler in the Medical Society of Greifswald,† the pharmacologist, Professor Schulz, entertained the society by quoting from a book of one Oswald Kroll, written at the beginning of the seventeenth century. There are recommended the lung of the fox against the disease of the lungs, the liver of the wolf for the ailments of the liver, and for eye troubles the eye of the ox, etc.

Now, gentlemen, let me tell you right here that the entire assumption is without any foundation. The treatment of myxœdema is valid upon another more solid basis than this cheap hypothesis which recommends a treatment of the diseases of the liver by the liver of the wolf, and impotence by the testicles of the donkey or sheep! On the contrary, I venture to state that all the therapeutic measures which have emanated exclusively from the wisdom of, say, similia similibus, and that means nearly all the animal extracts, are still far from being well-established facts. I shall not enter into a discussion of their merits. It will suffice to refer to the voluminous contradictory literature on the subject of testiculine, cerebrine, etc., or of the treatment of Addison’s disease with suprarenals, of leucæmia with the spleen, and of diabetes with the pancreas, etc. The positive statements are in the minority and are decidedly not assailable. Now contrast with those the reports on the infallible success of the treatment of myxœdema with thyroid! No, the sweeping hypothesis of similia similibus has no share in the brilliant results of the thyroid therapy; this is exclusively the fruit of well-considered biological experiments and clear, sharp clinical observations, as will be seen from the short outline of its history which I am now going to give.

M. Schiff,* as is now well known, was the first one (1859) to describe the complex of symptoms following the removal of the thyroid in dogs. Cachexia strumipriva, or operative myxœdema, in man was first described by Reverdin‡ and then by Kocher.§ In 1882 and 1883. Induced by these surgical experiences, Schiff* again took up his old experiments on dogs, and then made the observation that if the thyroid of a dog was grafted into the peritoneal cavity of another dog no untoward symptoms followed the removal of the thyroid in the latter animal. Schiff believed that the implanted thyroid persisted in the peritoneal cavity and assumed the function of the removed thyroid. With this interpretation the implantation could not be considered as a medicinal treatment; the removed thyroid being simply supplanted by another one in another locality, the procedure could be considered as somewhat analogous to skin grafting. Schiff’s experiments have been repeated and confirmed by v. Eiselsberg.|| Kocher* attempted the grafting of the thyroid in man, but did not succeed. Birchera, however, implanted a human thyroid successfully twice in one and the same person—a woman with cachexia strumipriva. The improvement following the first grafting lasted three months; after the second grafting the patient was in quite a normal condition for nine months, at the end of which tetanic symptoms again made their appearance. Acting upon the experiments of Schiff and v. Eiselsberg and without the knowledge of Birchera’s experience, Victor

Horsley* made the proposition of implanting sheep's thyroid in cases of myxedema and cretinism. This was indeed done in a number of cases of cretinism, and all the operating surgeons reported an unmistakable improvement following the grafting of the thyroid. Bettoncoute and Serrano,† however, have noticed a distinct improvement so rapidly as in twenty-four hours after the implantation. As in this short time certainly no vascularization of the implanted thyroid could have taken place, the improvement could not have been due to the secretion of the gland, but to the absorption of its juice. Here the idea sprang up of the therapeutic value of the juice of the thyroid. But to introduce thyroid juice into the body it was not necessary to implant the body of the thyroid and leave the process of extraction to the body of the animal; it is rather simpler to extract the juice and inject it into the animal. Moreover, the preparation of a thyroid juice was not at that time a new departure; J. R. Ewald‡ had used it some years before to study its effect upon normal animals. Of greater importance, however, were apparently the experiments by G. Vasale.* This investigator made intravenous injections of thyroid extract into dogs whose thyroid was removed; these injections prevented the outbreak of the tetanic condition. From this to subcutaneous injection was then only a short step, and this step was successfully taken by George R. Murray. He prepared a glycerin extract of the gland and injected it into a patient with myxedema with a marvelous result. The news spread rapidly, and the experiment was repeated many times with uniformly favorable results. If we consider the methods of administration of medicine, then we find that the intravenous injection stands in the first place; next comes the hypodermic application, and in the last place we find the administration per os. Accordingly, we shall have to consider G. Vasale, who introduced the intravenous injection of thyroid, as the real discoverer of the treatment of myxedema with the thyroid. But Vasale's communication remained apparently without any influence upon practical therapeutics; it was a biological experiment rather than a therapeutic measure. It was the surprising success of Murray which brought this new remedial agent to the attention of the physicians all over the world. His fame is well deserved.

The next important step, that of administration of the thyroid by the mouth, was made by Howitz. He reported it at the Scandinavian Congress of Physicians, June, 1892. This, however, remained practically unknown until the following October, when Mackenzie§ and Fox,¶ both independently of Howitz and of one another, reported at the same time the favorable results they had obtained by the administration of the thyroid per os.

The administration by the mouth seems to be now the universally accepted method.

You see, gentlemen, that the sweeping hypothesis of *similia similibus* had nothing to do with the birth and growth of the treatment of myxedema with thyroid. It was developed step by step by clearly preconceived biological experiments. By this method we should have arrived at all times at the same results. In no stage of its development had the thyroid therapy profited by the hypothesis underlying the therapeutics of the animal extracts, or, more correctly, organ therapy. Therefore this sweeping hypothesis has no right to claim the effective treatment with thyroid as a verifying consequence. Hence I say the mixing up of the thyroid with the so-called animal extracts is unjustifiable and misleading. Through that the thyroid therapy meets with an undeserved suspicion, and the organ therapy receives an unfounded support.

In this connection allow me to make the following remarks: The therapeutic principle of the thyroid differs in an important point from even the most promising of all the animal extracts, the antitoxines; the effect of the thyroid is not destroyed by digestion or heat, while that of the antitoxines is. One point, however, is common to both, and that is the method by which they were discovered. It was not the pathological anatomy, not the cellular pathology, not the all-dominating histology, nor the chemistry, nor the pharmacology which brought out the marvelous results; it was the biological experiment which gave us truly specific remedies—this should be a lesson to the thinkers, the philosophers in medicine.

The thyroid is a specific remedy for such pathological conditions as are due to the lack or insufficient action of the thyroid. We know now three such types: 1. Naturally acquired myxedema of the adult. 2. Myxedema acquired by operation, or cachexia strumipriva. 3. Congenital myxedema and myxedema acquired in early infantile life, or cretinism. In all the three forms of myxedema the administration of the thyroid effects an undoubted improvement. It is my task to-night to deal with the naturally acquired myxedema of the adult.

Since I spoke to you on this subject, i. e., in the course of last year, many more cases of myxedema have been reported in which all recognizable symptoms of the disease were removed by feeding the patient with thyroid. There are also a few unsuccessful cases on record, but we have sufficient reason to doubt the value of such reports. The literature contains statements which are capable of shedding light upon such reports. Starr* tells us of a case which had been treated by a physician with thyroid for about eight months without any success, while in the hands of Starr the same patient rapidly improved under the administration of the thyroid tablets of Burroughs, Wellcome, & Co. In a recent paper of Ewald's † it is stated that in one case the use of a thyroid extract for four months gave hardly any results, while the tablets mentioned soon produced an unmistakable effect. Of great interest is the report of Marie and Guerlain.† A patient had been given "thyroid" for a long time without any success. A mi-

crosopic examination revealed the fact that the patient had received all along the submaxillary gland. The real thyroid soon brought the desired result. This reminds one of the experiments of Kaufmann, which in the belief of this author should refute the assertions of Schiff concerning the effect of the removal of the thyroid in dogs. Fuhr has shown that Kaufmann constantly removed only the submaxillary gland. It seems that we are indeed justified in assuming that in cases where the thyroid fails to improve, either the diagnosis of myxedema was not correct or there was somewhere a fault in the method of administration.

By the term "cure" is, of course, not meant a radical cure. On the contrary, all reports agree that a continuation of the thyroid treatment, though at longer intervals, is required to keep up the good results attained. And it is very plausible. The normal thyroid secretes constantly and continually an indispen-able substance; after removal of the thyroid the substitute should also be administered constantly and perhaps also continually. The thyroid juice, however, has apparently a cumulative effect—i.e., a residue of the thyroid principle present in the body of the animal is not excreted at once. An administration of the thyroid at longer intervals, therefore, might be sufficient to produce a continual effect. As to the length of the interval between the accomplished improvement and the starting again with some administration of thyroid, opinions seem to differ. Some speak even of a whole year. This seems to me to be quite exaggerated. The normal storage of the thyroid principle in the body certainly becomes exhausted in a short time. The tетanic symptoms appear in animals and man only a few days after the removal of the thyroid. I have seen in a dog fed on raw meat the typical convulsions appear in forty-eight hours after the operation; the normal surplus was consumed in two days. There are, however, many outside factors capable of determining the time in which the accumulated thyroid becomes exhausted—for instance, the character of the food and the season of the year. According to my experience the myxedema patient requires in winter larger doses repeated at shorter intervals than in summer. Horsley's experiments on the influence of the temperature upon the outbreak of cachexia strumipriva in donkeys and sheep are well known. But I shall not dwell here any longer on these points.

It is generally stated that an increase in weight is an indication to start the treatment again. This is certainly not correct for all the cases. An increase in weight is often observed while still continuing the thyroid in full doses, especially after the first rapid loss in weight; the improved health is the cause of gaining normal flesh. I have seen it in my own experience, and similar statements are made by Leichtenstein and others. I shall rather put forward the complaint of feeling cold as a sure indication of the beginning of the return of myxedema. I have noticed the appearance of this complaint sometimes even before the weight has shown an increase, and a few small doses of thyroid were sufficient to soon do away with this chilliness. The chilliness is an important symptom in myxedema, and is independent of the changes in the skin or the subcutaneous tissue.

In reference to the preparations and the mode of administration of the thyroid, it may be stated that at present the powdered substance of the thyroid is almost universally in use. We can hardly speak any more of thyroid extracts. In this country the preparations of three firms seem to be in vogue—Parke, Davis, & Co., Armour & Co., and the London firm of Burroughs, Wellcome, & Co. The latter offer the thyroid exclusively in the convenient form of tablets. In the English and German literature we often read of these tablets; in this country also they are preferred by some. My own experience has been less favorable—the effect was inconstant. Of Parke, Davis, & Co.'s preparations, I have employed so far only the desiccated powder. In the myxedema case that I reported to you last year I had again and again to return to the powder of Parke, Davis, & Co., which almost brought the desired effect. Of Armour's preparations, I have used both the powder and the tablets. The latter have not given me satisfactory results. The tablet form is not reliable, anyhow; they often do not dissolve, and then again it might happen that an accumulated large number would accidentally dissolve at once and produce a dangerous condition. The powder is furthermore preferable because you can prescribe different quantities at your own will, while fractions of the small tablets can certainly not be measured exactly. The powder is administered in wafers or in capsules, if it is simply put into the capsules without being previously made into a mass. It should be borne in mind that the weights of the preparations of the different firms have a different meaning. Parke, Davis, & Co. prepare fifteen grains of powder from one thyroid, while Armour & Co. prepare only six grains. Thus one grain of Armour & Co.'s powder is equal to about two grains and a half of the powder of Parke, Davis, & Co. For the tablets of Burroughs, Wellcome, & Co. it is maintained that they represent one sixteenth of a thyroid and contain five grains of the substance of the gland. Then one tablet would be about equal to one grain of the powder of Parke, Davis, & Co., and from an eighth of such a tablet Bramwell has seen good results!

The dose of thyroid is by no means an indifferent question. There can be no doubt that dangerous conditions may be brought about by feeding with thyroid; there is no lack of such reports in the literature. But such states were produced by overloading, and occurred oftener in the beginning of the new era than they now occur. The dangerous conditions are characterized by stenocardiac attacks, with very rapid and hardly perceptible pulse and great prostration; the extreme feebleness sometimes con-

* Tablets similar to those of Burroughs, Wellcome, & Co. are now also put on the market by Fairchild Brothers & Foster.
† Med. Monatschrift, April, 1894.
times for days. I am of the opinion that dangerous conditions like these can positively be avoided if the start and progress of the treatment are made with sufficient care. Not more than a fifteenth of a thyroid (about equal to a grain of the powder of Parke, Davis, & Co.) three times a day should be the initial dose. The increase should be gradually and carefully made under the constant guidance of pulse and temperature. The worst attack which could be met with under such careful procedure would consist of vomiting, precordial oppression, myasthenia, and tremor. These attacks are easily remedied by discontinuing the use of the thyroid and by rest in bed for a few days. Under slow and moderate treatment success is also sure, though it is attained a little later; for this we are sufficiently compensated by the well-being of our patient. Certain disadvantages, however, are even under the most conservative treatment unavoidable. Some acceleration of the pulse, fatigue, and slight tremor of the limbs are among the earliest unpleasant manifestations; headaches, and pains in the entire body, follow soon; a vexing urticaria appears in some persons after a few small doses of thyroid. All these complaints, however, are accessible to treatment. Iron and strychnine for the general weakness, salicylate of sodium and phenacetin for the pains and aches, are very effective. For the urticaria I have found pilocarpine (a sixteenth of a grain three times a day) very satisfactory.

I wish to add here briefly one more observation I believe I have made. If a sure working dose is given without interruption for a long time its effect seems to be gradually diminished; chilliness, increase of weight, obstruction, etc., gradually make their appearance while the same dose of thyroid is still continued. If, then, the administration of the thyroid is discontinued for some time, we observe at the resumption a distinct effect even from doses smaller than were given before the intermission. This looks as if the body had got accustomed to the reaction of the foreign thyroid introduced. On the other hand, the body certainly does not lose its susceptibility to the products of its own thyroid.

The discussion of the thyroid treatment of surgical myxoedema does not belong to the province assigned to me. I also have to refrain from entering into a consideration of congenital myxoedema, as it belongs to the department of neurology. I wish, however, to avail myself of the present opportunity for reporting a case of cretinism now under my care:

L. T. is now a boy of sixteen years. He was born in London of healthy parents not related to each other. When four weeks old he had his first attack of convulsions, which thenceforth never left him. A number of neurologists pronounced him to be a typical idiot. When I saw him for the first time, about a year ago, he presented about the following status: His size was that of a boy of about eleven or twelve years, but abnormally bulky; he had a weight of one hundred and twenty-five pounds. Face, neck, body, and especially the limbs, were covered with edematous swellings; a digital pressure did not leave any mark. Both mammas were of an enormous size, like that of a fully developed fat woman. The tongue protruded between the decayed teeth. The cranium was not abnormally shaped. He seemed neither to see nor to hear any thing; a closer observation, however, revealed the fact that the senses were not destroyed; it was only a lack of perception. He did not fix anything; his gaze was vacant; no sound however loud seemed to attract his attention. His vocabulary consisted of one word, "mimi," which was often repeated without any meaning. He often seemed to be in a rage, but hit only himself. He was greedy, but apparently without any preferences; was constantly constipated; the faces were tape-like in shape. He urinated in his clothes. There had been nearly every five minutes clonic or tonic convulsions, especially of the muscles of the neck, and even in the intermission the head was nearly in constant movement, but it seemed to have a voluntary character. Besides, he had every day quite a number of real epileptic fits; he fell quite heavily, and was injured many a time, of which the scars on his head are telling proofs. My diagnosis was sporadic cretinism. It was impossible to ascertain whether the thyroid still existed, on account of the considerable swelling of the neck. I ordered the thyroid powder of Parke, Davis, & Co., which was given to him in his food. The first success was a striking one. From the second day of the administration of the thyroid there was no longer even a trace of the former convulsions. The weight was reduced to less than a hundred pounds, the bowels started moving regularly, and with the faces of normal shape. In the third week, however, the boy began to show an extreme restlessness; he screamed and yelled constantly, clung to the mother, and appeared to be in great distress. It was apparent that he was suffering great pain. The parents had given him much more of the preparation than I had ordered—the father of the crotin is a druggist. I then changed to the tablets of Burroughs, Wellcome, & Co., of which three a day were given. The restlessness indeed subsided, but the weight began to increase again. The further treatment varied in many ways; but I shall not bother you with the unimportant details of the further course of this case, but will give you a short account of the boy's present condition. It is a year now that he has been under nearly constant thyroid treatment; he now gets Armour's tablets; powders or capsules he refuses to take. He looks now rather slender, only the right leg is somewhat thick yet. In front of the trachea there is a striking recess, and no trace of a thyroid can be discovered. He has grown about an inch. His bowels move rather frequently; the same is true of his urinating. The parents maintain that there is an odor about the boy which resembles very much the odor of the thyroid. In the last few weeks some slight twitchings have appeared now and then. Mimi is still the only word of his vocabulary, but it often seems that he associates some sort of a meaning with it. There can be no doubt now that he perceives objects around him. He follows with his eyes when he is shown something, and turns his head when he hears a noise, or even when he is spoken to; but the fixed attention lasts only a couple of seconds. He caresses his mother when he wants something of her. He goes to his father when his mother sends him there and promises to fetch cake for him. At the table he picks the meat out from among the potatoes; he rejects the pits of the plums; he has a preference for cake, knows where it is to be found, and draws his mother thither, but does not take any himself. He plays with the children, strikes the girl, who does not retaliate, and takes care not to engage in a quarrel with the boy. In short, there are traces of newly acquired intelligence, but they are as yet indeed only traces, and in no proportion to the striking physical change.

The primary symptoms of myxoedema may be divided into three groups: changes of the skin, changes in the subcutaneous tissue, and changes in the normal activity of the nervous system. Under treatment with thyroid the symp-
WATERS: A REPORT ON SALOPHEN.

[June, 1894]

A REPORT ON SALOPHEN.

BY BERTRAM H. WATERS, A. M., M. D.,
HOUSE PHYSICIAN TO THE PRE-BYTHIAN HOSPITAL, NEW YORK.

The advocate of a new remedy must bear the burden of proof. To insure its reception it must be shown that a new drug not only fulfills indications and meets conditions as well as those already in use and perhaps favorably regarded, but also that it is more efficient or freer from disadvantages which attend the use of its rivals. The presentation of salophen to the medical profession as an antirheumatic meets precisely these difficulties, and the object

posum with thyroid. Of course, only small doses come into consideration. When larger doses are used, the heart may be affected either by the considerable loss of substance which the entire body (and the heart) sustains, or perhaps also by a direct toxic effect of the thyroid upon the heart. The cases of fatty heart I have so far had an opportunity to treat with thyroid have been of a moderately severe type, but the results have indeed been very satisfactory. I shall illustrate this by a brief report of one of my cases:

Mrs. P., a married lady of forty-eight years, had a weight of one hundred and ninety-two pounds, and was below middle height. Her weight had increased gradually for years, and made her feel very uncomfortable. She was suffering, as she put it, with asthma. In the course of the winter of 1893-1894 her condition became alarming. She could hardly walk the stairs; the slightest exertion made her breath very short and produced severe palpitation. She was constantly bathed in perspiration. She could stay in bed only in a half-reclining position. An examination revealed clear but hardly audible heart murmurs; the size of the heart could not be ascertained, on account of the very large breast. In the lungs there were some sibilant and moist rales. Pulse frequent, small, and soft. Extensive edema of both legs; urine normal. Diagnosis, fatty heart. I gave her thyroid (P., D., & Co.), two grains a day. On the very next day an improvement in her breathing could be distinctly noticed. The patient was enthusiastic about the remedy. Within the next few days she sent word that I should not call; she intended to call on me. She came after a week, but with complaints of tremor, weakness, headache, etc. The secret was, she increased, against my strict orders, the dose to ten grains daily! It was only with difficulty that I could induce the patient to discontinue the use of the medicine for a few days. The thyreoidism disappeared soon, and we again started with two grains daily, increasing it gradually to six grains a day, and giving her at the same time all along a mild preparation of iron. The patient lost eighteen pounds in three months and a half, and the edematous swellings of the limbs disappeared entirely. She does not experience any more difficulty in breathing, palpitation, fatigue, or profuse perspiration. She goes up and down stairs in her house many times a day; walks long distances; attends to her duties in and outside of the house; her appearance and behavior are entirely changed. Mrs. P. has not taken any thyroid for the last eight months; her condition, nevertheless, continues to be favorable. She did not cough even once during the entire winter, while in preceding years she hardly stopped coughing all winter.

66 East 124th Street.
of this paper is to report its use and the clinical results obtained in the actual practice of hospital wards. The test seems severe enough, and the report of the cases, especially when compared with some in which the older remedies have been used, offers a fair comparison.

The drug itself is a combination of salicylic acid and an innocuous phenol. Thus it has as its base the substance which has come to be considered most useful in rheumatic affections, and as an adjuvant one of well-known antipyretic properties.

Acute rheumatic fever may present such distressing symptoms, may be complicated in so many and often serious ways, and may be of such duration, that one naturally seeks for a remedy which will—

1. Relieve promptly the acute suffering from both local and constitutional conditions.

2. Effect a limiting or curative influence upon the disease.

3. Prevent complications.

4. Be well borne by the patient.

5. Be agreeable in administration.

The cases reported here are taken at random from those occurring in the wards of the Presbyterian Hospital, New York. The cases reported occurred in the service of Dr. Andrew H. Smith, to whom I am indebted for permission to publish the report, and who coincides perfectly with the conclusions. In many instances the records are incomplete, but such as can be obtained are presented. Cases have been chosen in which other diseases were not concomitant, in which acute local conditions and pyrexia were present, and which were in fair physical condition. They will be considered with reference—

1. To the rapidity with which the joint symptoms were relieved and the temperature reduced.

2. To the duration of the disease.

3. To the occurrence of complications.

4. To the effect of the administration of the drug upon the stomach and the kidneys, and with regard to the constitutional toxic effects of salicylic acid.

Either fluid or nitrogenous diet was used.

In all cases calomel in doses of from three to five grains was administered, followed by a saline purge. The drug was given dry upon the tongue, followed with water or milk. In most of the cases an alkali was given, either sodium bicarbonate or a combination of several of the potassium salts, and, in some, morphine or immobilization of the joints was used in the first twenty-four to forty-eight hours for relief of the acute joint tenderness. As a rule, some note has been made of the sex and age, of previous attacks of the disease, the duration of the trouble, the joints involved before admission, the physical condition and temperature of the patient at that time, in the hope that thus a better picture might be drawn of the severity of the affection and of the general condition of the patient. This will be useful in estimating the efficacy of the drug, and in comparing it with other forms of the salicylates.

1. Male, twenty-one years of age; one previous attack. Duration of illness three weeks. Temperature on admission, 102°F. Physical examination negative. Joints involved: ankles and knees. Treatment, a hundred and twenty grains of salophen in twenty-four hours. Temperature normal, and all local symptoms relieved on the fifth day. Salophen reduced to sixty grains. Duration of treatment nine days.

2. Male, thirty years of age; no previous attacks. Duration of illness three days. Temperature on admission, 104°F. Physical examination negative. Joints involved: ankles, knees, left wrist, right shoulder, and right metacarpals. Treatment, a hundred and twenty grains of salophen daily. Temperature normal on the ninth day. Salophen reduced to ninety grains a day. On the eleventh day it was reduced to sixty grains; on the twelfth day the patient was allowed a diet and to sit up. Duration of treatment twenty-five days.

3. Male, seventy years of age; two previous attacks. Duration of illness two days. Temperature on admission, 102°F. Physical examination: pulmonary emphysema. Joints involved: right knee and both ankles. Treatment, ninety grains of salophen daily. Temperature normal on the fifth day. Treatment was discontinued two days later. Duration of treatment twenty-four days.

4. Male, thirty-three years of age; no previous attacks. Duration of illness six days. Temperature on admission, 101°F. Physical examination negative. Joints involved: ankles and wrists. Treatment, a hundred and twenty grains of salophen. Two days later the symptoms were relieved. Temperature normal on the fifth day. Patient was allowed a diet. Next day he was allowed to sit up. Duration of treatment twelve days.

5. Male, forty years of age; one previous attack. Duration of illness a month. Temperature on admission, 103°F. Physical examination revealed cardiac hypertrophy, emphysema, and bronchitis. Joints involved: knees, hips, shoulders, and elbow; no effusion. Treatment, a hundred and twenty grains of salophen a day. Temperature normal on the eleventh day. Salophen reduced to forty-five grains on the eighth day. On the thirteenth day treatment was discontinued. On the fourteenth day patient was allowed a diet, and sat up out of bed. Duration of treatment nineteen days.

6. Female, twenty-nine years of age; several previous attacks. Duration of illness seven days. Temperature on admission, 102-8°F. Physical examination showed mitral regurgitation. Joints involved: knees, right wrist, and ankle; no effusion. Treatment, a hundred and twenty grains of salophen daily. In forty-eight hours the symptoms were almost entirely relieved. Temperature normal on the seventh day. On the eighth day a diet was allowed. On the tenth day the salophen was reduced to ninety grains daily. On the twelfth day the salophen was discontinued. On the fifteenth day the patient was allowed to sit up. Duration of treatment twenty-two days.

7. Male, thirty-eight years of age; one previous attack. Duration of illness two weeks. Hips, shoulders, and right wrist have been painful. Temperature on admission, 102-2°F. Physical examination negative. Joints involved: ankles and knees; some effusion in each. Treatment, a hundred and twenty grains of salophen. In forty-eight hours the patient was comfortable, with a temperature of 100°F. Temperature normal on the fourth day. On the sixth day patient allowed up. Duration of treatment sixteen days.

8. Female, thirty-five years of age; no previous attacks. Duration of illness five weeks. Hands, knees, ankles, and toes joints affected. Temperature on admission, 102-8°F. Physical examination negative; a slight febrile albuminuria was present. Joints involved: hands, feet, and knees; no effusion. Treatment, a hundred and twenty grains of salophen. In twenty-four hours the pain was greatly relieved. Temperature normal.
on the fifth day. Salophen reduced to forty-five grains. On the sixth day salophen was discontinued. On the seventh day the patient was allowed a diet and to sit up. Duration of treatment eleven days.

9. Male, thirty-five years of age; no previous attacks. Duration of illness three weeks. Right knee and left elbow involved. Temperature on admission, 108° F. Physical examination negative. Joints involved: right wrist, left ankle, and knees. Treatment, a hundred and twenty grains of salophen daily. On the third day the pain was much relieved. On the fourth day the patient was quite comfortable. Temperature, 99° F. On the sixth day salophen was discontinued. Temperature normal on the seventh day. On the eighth day the patient was allowed up. Duration of treatment fifteen days.

10. Male, eighteen years of age; no previous attacks. Duration of illness four days. All major joints involved. Temperature on admission, 103° F. On physical examination the heart showed hoarse murmurs; patient very anemic and in poor condition. Joints involved: ankles, knees, right hip, wrist, elbow, and shoulder. Treatment, a hundred and twenty grains of salophen daily. Temperature normal on the sixth day. On the seventh day no local symptoms present. Duration of treatment five weeks.

11. Male, twenty-four years of age; no previous attacks. Duration of illness two weeks. Left knee, ankle, and right arm involved. Temperature on admission, 102° F. On physical examination the heart showed aortic and mitral diseases. Treatment, ninety grains of salophen daily. Temperature normal on the sixth day. Patient up on the tenth day. Duration of treatment thirteen days.

12. Female, twenty-two years of age; no previous attacks. Duration of illness, one week. Knees and ankles involved. Temperature on admission, 105° F. On physical examination the heart showed some hoarse murmurs; very anemic. Joints involved: left shoulder, knees, wrists, and metacarpals. Treatment, a hundred and eighty grains of salophen daily. During the first two days a little morphone was used. Temperature normal on the fourth day, with no pain. On the ninth day treatment with salophen was discontinued. Duration of treatment nineteen days.

13. Male, nineteen years of age; one previous attack. Duration of illness three weeks. Joints affected: ankles and knees. Temperature on admission, 101° F. Physical examination showed cardiac hypertrophy and mitral regurgitation. Joints involved: knees subacutely. Treatment, a hundred and sixty grains of salophen daily. Temperature normal on the fourth day. On the sixth day all symptoms relieved. On the twelfth day the patient was allowed up. Duration of treatment sixteen days.

14. Male. No history. Temperature on admission, 101° F. Physical examination shows some mitral regurgitation. Joints involved: right knee and left shoulder acutely, other joints tender. Treatment, a hundred and twenty grains of sodium salicylate daily. Temperature normal on the sixth day. On the tenth day medication was discontinued. On the fourteenth day the patient was discharged. Eleven days later the patient returned, having had a relapse, with a temperature of 102° F. Ninety grains of salophen was then given, and on the fourth day the temperature was subnormal. On the eleventh day treatment was discontinued and the patient made a good recovery. Duration of treatment fifteen days.

15. Female, eleven years of age; no previous attacks. Duration of illness five days. Left ankle and right wrist affected. Temperature on admission, 100° F. Physical examination negative. Joints involved: left knee, ankle, and right hand. Treatment, sixty grains of sodium salicylate daily. Temperature normal on the twelfth day. Duration of treatment twenty-three days.

17. Male, forty-three years of age; no previous attacks. Duration of illness a week. Right knee affected. Temperature on admission, 101° F. Physical examination of the heart shows some mitral disease. Joints involved: right knee, with effusion. Treatment, a hundred and twenty grains of sodium salicylate daily. Temperature normal on the sixth day, but considerable gastric irritability was experienced, and there was rather marked reduction of the amount of urine passed. Duration of treatment nine days.

18. Female, thirty years of age; numerous previous attacks. Duration of illness five weeks. Knees, ankles, and elbows affected. Temperature on admission, 100° F. Physical examination negative; urine shows albumin and casts. Treatment, a hundred and twenty grains of sodium salicylate daily. Temperature normal on the fifth day, but rose afterward to 100° F., with continuance of symptoms subacutely until the tenth day. Ol. gaultheriae was then given, with relief of symptoms. Duration of treatment fifteen days.

19. Female, sixteen years of age; no previous attack. Duration of illness three weeks. Ankles and knees affected. Temperature on admission, 103° F. On physical examination the heart showed some hyperpertryph and mitral disease. Treatment, a hundred and twenty grains of sodium salicylate. Temperature normal on the eighth day. Treatment discontinued. Two weeks later, after subacute symptoms, there was a relapse, with a temperature of 102° F. Treatment resumed. Temperature again normal in four days. Duration of treatment fifty days.

21. Male, forty-nine years of age; three previous attacks. Duration of illness ten days. Right ankle and left knee affected. Temperature on admission, 101° F. Physical examination negative. Urine shows albumin and casts. Joints involved: knees, elbows, and right shoulder. Treatment, ol. gaultheriae, in daily. On the twelfth day gastric disturbance was noted, and the disease had progressively invaded other joints. On the fourteenth day temperature normal. Duration of treatment twenty-six days.

22. Female, twenty-eight years of age; no previous attacks. Duration of illness two weeks. Toes and knees affected. Temperature on admission, 104° F. Physical examination negative. Joints involved: left foot and knee. Treatment, ol. gaultheriae, in daily. Temperature normal on the twelfth day. Still some joint tenderness. Patient continued to have subacute symptoms, which finally yielded to the iodide of potassium and colchicum. Duration of treatment forty-seven days.

23. Female, twenty years of age; no previous attacks. Duration of illness four days. All the major joints affected. Temperature on admission, 102° F. Joints involved: knees, ankles, shoulders, wrists, and right knee, with effusion. Treatment, ol. gaultheriae, in daily. Temperature normal on the seventh day, but afterward ranged from 99° to 101° F., with subacute
SHANDS: INFLAMMATORY RHEUMATISM OF THE ANKLE.

May 25, 1895.

SEVERE PAIN AND SPASM OF INFLAMMATORY RHEUMATISM OF THE ANKLE RELIEVED BY IMMOBILIZATION OF THE JOINT.

By A. R. SHANDS, M. D.,

WASHINGTON, D. C.,

PROFESSOR OF ORTHOPEDIC SURGERY,
MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY.

Having read the very interesting and instructive paper on the treatment of Sprained Ankles by Dr. V. P. Gibney, of New York, published in the New York Medical Journal on the 16th of February, 1895, it occurred to the writer that it might be of interest to the profession to know of a most excellent result recently obtained in a very severe and painful case of inflammatory rheumatism of the ankle and foot by applying the method of treating sprained ankles, as advocated in the paper above referred to, together with complete immobilization of the joint by means of a plaster-of-Paris case.

On November 18, 1894, I was consulted by Dr. S. C. Busey, of this city, regarding a case of inflammatory rheumatism of the ankle and foot that was under his care, and which up to that time had baffled all attempts to produce any permanent relief of the pain and spasm about the offending joint.

The patient, a physician of middle age, was attacked with rheumatism, soon localizing itself in the left ankle and foot, five weeks previous to the consultation. He had had a very thorough course of treatment, consisting of the usual antirheumatic remedies, with little if any alleviation of the most distressing symptoms—pain and spasm.

Still the foot and ankle continued to swell, pain and spasm to increase, until at the time that I first saw him the foot was at least one third larger than its fellow. Pain was excruciating and had only been relieved by morphia, while all the muscles of the whole limb could be easily thrown into a state of clonic spasm by the least attempt of passive motion of a single toe, or by the least jar to the patient's bed. So easily was this condition of clonic spasm produced, and thereby causing excruciating pain, that the patient dreaded the approach of any one toward his bedside; he would at once begin to demonstrate with any one who attempted in any way to move or change the bedclothes. He had remained in one position until there was marked tenderness about the most dependent points of pressure on the side of the body with the lame foot.

All the normal depressions about the malleoli were obliterated, and, as the swelling extended from about two inches above the malleoli to the tips of the toes, the arch of the foot presented very much the appearance of a typical flat-foot, which did not exist, however, for after the swelling had subsided the arch of the foot was found to be perfectly normal. Upon close inspection there was found to be but very little synovial inflammation, and that just under the internal malleolus. It was plainly seen that the swelling was due to edema and infiltration of the peri-articular structures caused by the rheumatic inflammatory process, which had at that time continued unabated in spite of the very thorough medical treatment above referred to.

The next most prominent feature of this case was the very marked atrophy of both calf and thigh muscles of that limb.
This case illustrates to my mind most beautifully what is called by Sir James Paget "reflex atrophy," being caused by disturbance to the trophic centers by the reflex spasm. The atrophy in this case could in no way be accounted for from non-use of the limb, for the patient had been confined to bed from the first.

The temperature of the patient had averaged daily from 100° to 102° F.

Upon inspection I at once concluded that this was a case that would be benefited by strapping the foot and ankle with strips of adhesive plaster after the manner that is used at the dispensary of the Hospital for the Ruptured and Crippled, New York, as advocated by Dr. Gilney in the paper above referred to. This method I had seen give most excellent results during my connection with the staff of that institution.

This treatment was at once suggested, together with immobilization of the foot with a plaster-of-Paris case, and was readily agreed to by both the patient and his physician. The strips of adhesive plaster were applied by starting the first one from the plantar surface of the base of the little toe and carrying it diagonally across the dorsum of the foot, ending it at the outer border of the heel. The second strip was started from the plantar surface of the base of the great toe, carrying it likewise diagonally across the dorsum of the foot, ending it at the inner border of the heel. This was continued, overlapping each strip about one half with the next one in order, until the whole foot and ankle were incased. Over this was applied a cheese-cloth bandage, next there was applied a thick layer of absorbent cotton extending from the tips of the toes to the tuberosity of the tibia, then a cheese-cloth bandage over the cotton; then finally the application of a snugly applied plaster-of-Paris case, extending from the tips of the toes to the tuberosity of the tibia, completed the dressing.

This dressing was applied about the middle of the afternoon; that night the patient, fearing that the local dressing would not give the much-desired relief, took a small dose of morphia, which, with the perfect rest afforded the foot, produced an excellent night's sleep. The next day he was very comfortable, being able to turn about in bed, a thing that he had not been able to do for several weeks. The second night after the foot had been immobilized he had a perfectly comfortable night's rest without morphia. Late in the afternoon of the second day I had a note from him, saying that his foot seemed loose in the plaster-of-Paris case, and that the pain and spasm had returned, but in a mild degree as compared with that of two days previously. About eight o'clock that evening I found just the state of things he had described in his note—foot loose in the dressings, and that there was a return of pain and spasm. This condition of affairs, I was quite sure before touching him, was due to the fact that, under the equable pressure that had been afforded the edematous and infiltrated tissues by the adhesive plaster strapping, the swelling had subsided, and that the plaster case was no longer affording support. At once it was decided to remove all of the dressings and apply another set to fit the foot snugly in its changed condition; the patient did not agree readily to this, his extreme modesty (1) causing him to insist that he did not wish me to have so much trouble on his behalf; but to my mind it was clearly a case on his part of being satisfied with doing well as compared with two days previously; the true reason was, he dreaded my handling the foot, fearing the pain would return.

After all the dressings were removed the foot was found to be but very little larger than its fellow; it truly seemed wonderful that so much edema and infiltration could have disappeared in so short a time—just a little over forty-eight hours. An entirely new dressing was applied as above described; that night the patient rested well, on the following day was able to sit up, and on the fourth day was able to get about the house on crutches. The second dressing was allowed to remain on one week, when it was removed, and, as all pain and spasm had disappeared, it was not renewed, but instead there was applied a circular stockinet bandage to the foot and leg, and the patient was instructed to use the foot in locomotion as much as he could without causing pain. From this time on there was a rapid and uninterrupted recovery, and in one week patient called at my office, where there was found some pain on passive motion about the medico-tarsal joint, but this gradually wore away under the influence of gentle massage and passive motion, and very soon thereafter the patient was able to resume his duties—that of a busy gynecologist.

It should be mentioned that while the patient had been having a daily rise of temperature ranging from 100° to 102° F., after this dressing was applied the temperature never went above normal, no other antipyretic being used.

While the treatment of acute articular rheumatism by immobilization is not new, yet I do not believe it is in very general use. I have been unable to find a report of any cases thus treated. Professor Osler, in his Practice of Medicine, speaks of having seen very excellent results obtained in this very painful affection by German physicians from the use of immobilization by means of plaster of Paris. So far as I know no one has used the method of strapping the joints with adhesive plaster in connection with the plaster-of-Paris case. This is undoubtedly the most perfect way of obtaining absolute rest for the inflamed joint, and at the same time aids the absorption of the pathological secretion.

To be sure of relieving the spasm it is necessary to extend the dressings up to the popliteal space, for in this way you put at perfect rest all the calf muscles. Some who have not had an extensive experience in treating disused joints may fear producing some degree of ankylosis by thus immobilizing joints; on the contrary, immobilization during an acute inflammatory process will limit any tendency to production of ankylosis. Rest to a joint will not produce ankylosis; the product of an inflammatory process is what produces ankylosis; therefore it must follow that anything that will cut short the inflammation must limit the ankylosis. It is a well-recognized fact in surgery that all wounds heal more kindly and rapidly under perfect rest.

The explanation that Dr. Gilney gives of the theory of this method of treating sprained ankles—viz., "the equable support given to the tendons and ligaments about the joints results promptly in the resolution of all effusion"—is surely the correct explanation, as is well evidenced in the case here reported.

Accepting this theory, I think all who will apply this method of strapping joints affected with acute rheumatism accompanied with pain and spasm, and then give perfect rest by means of a plaster-of-Paris case, will be rewarded with excellent results. This treatment in the early stage of the disease should be regarded as supplementary to the proper medical treatment.
THE TREATMENT OF ACUTE PNEUMONIA BY "ICE CRADLING."

In the British Medical Journal for May 11th Dr. P. Blaikie Smith, of the Aberdeen Royal Infirmary, reports two cases in which he employed a method of treatment thus entitled with good results. The subject of ice cradling, he says, first attracted his attention about two years ago, when Dr. W. Soltan Fenwick reported encouraging results following the adoption of certain antipyretic procedures in cases of acute sthenic pneumonia. Out of one hundred and eight cases treated by sponging or ice cradling the mortality amounted to ten per cent., while the death-rate in five hundred and fifty-two cases treated in the ordinary way reached twenty-three per cent.

During the two months preceding his report Dr. Smith has had several cases of acute pneumonia in which his method of carrying out the treatment was practically the same as that described by Dr. Fenwick. The patients were placed in bed, and on the body and legs two large cradles were arranged extending from the shoulders to the feet. Six or eight small pails filled with ice were attached to the arches of the cradles; a thermometer was hung from the centre of the upper cradle, and both the cradles were covered, first with a blanket, then with a waterproof, and lastly with the usual covering. The pails were refilled as the ice melted, and the temperature of the air under the cradles, of the ward, and of the patients was taken every four hours; the temperature of the air under the blankets before the cradles were placed in position was also taken. This treatment was maintained until the patient’s temperature became normal. These cases, says Dr. Smith, were examples of acute sthenic pneumonia, all of them complicated with pleurisy, and in one instance the pneumonia was double. All the patients recovered.

The first case was that of a man, aged thirty years, who was suffering from inflammation of the left lung, complicated with pleurisy. His pulse was 106, his respiration 41, and his temperature almost 103° F. Before the treatment began the temperature of the air under the blankets was 88°. When simple cradling had been employed for four hours it had fallen to 72°, after the employment of ice cradling for the same length of time it had fallen to 62°, and afterward during the treatment it ranged between 60° and 70° until the eighth day, when a crisis occurred, and the treatment was discontinued. With regard to the effect of the treatment on the bodily heat, says Dr. Smith, no marked depression was observed. The temperature declined gradually and in a somewhat fluctuating manner, the fall becoming more rapid as the crisis approached. The pulse and respiration rates, and their ratios to each other, seemed practically unaffected by the treatment.

The second case was that of a man with pneumonia of the apex of the right lung complicated with pleurisy. The bed temperature was not taken in the beginning, but after the cradles had been in operation for two hours (without ice) it was 80° F. and the patient’s temperature 105° 4°. The pails were then filled with ice, and in two hours more the bed temperature had fallen to 73°, but there was no material change in the patient’s temperature. For the next few days, until the eighth day, when the crisis took place, the ice cradling was maintained, with the results that the bed temperature fluctuated between 70° and 65°, and at the end of that time, the cradling having been discontinued, the thermometer under the blankets was 87°. In this case, says the author, the effect of the treatment on the patient’s temperature was not at all evident. For three successive afternoons the thermometer rose to over 105°, the cradle temperature rising with it, but it finally fell rapidly on the eighth day to normal. With regard to the pulse and respiration rates, the influence of the ice seemed more apparent, for with a temperature of 105° the pulse was only 100 and the respirations ranged between 30 and 35 a minute.

Dr. Smith states that he is unable to discover any marked signs of improvement following the complete establishment of the treatment. There was no sudden fall of temperature, but, although there was no decided reduction in the temperature, the pyrexia (even in one case where both lungs were extensively involved) did not attain a great height, and he is inclined to think that the treatment exercised a restraining influence on the bodily heat. The pulse and respiration also seemed to be under restraint, for the heart’s action was in no case unduly rapid or weak, and the breathing was never a source of anxiety. The patients, as a rule, felt comfortable under the treatment, although one or two complained of cold feet. In one patient inordinate perspiration was a marked feature, but the discomfort arising from this symptom disappeared at once with the establishment of the ice cradling.

Regarding the means by which the antipyretic results were brought about, the author thinks that a twofold influence was at work—that of the air under the cradles and that of the ice pails. It is doubtful, he says, which of the factors was the more powerful, although he inclines to the belief that the lowering of the temperature produced by the cradles was greater than that due to the melting of the ice.

Judging from what he has seen of the procedure, Dr. Smith is disposed to recommend ice cradling as a mild form of antipyretic treatment, suitable for sthenic cases of acute pneumonia, for it is easy of application, is not violent in its effects, is not fatiguing to the patient, and is readily carried out in any disease where a restraining influence on pyrexia and its attendant symptoms is desired.
THE MANDATORY TEACHING OF TOXICOLOGY TO URCHINS.

Dr. James H. Meehan, the health officer of the city of Niagara Falls, has sent us an important letter giving the text of a bill which at the time of his writing, May 15th, had been passed by both houses of the State Legislature and was in the Governor’s hands. Dr. Meehan adds some judicious and wholesome comments of his own the spirit of which we shall endeavor to bring out in this article. What the Governor has done with this pacific enactment, we do not know, but we think he has too much sense to allow it to become a law. It prescribes that “the nature of alcoholic drinks and other narcotics,” and their effects on the human system, shall be taught in not fewer than four lessons a week for ten or more weeks in each year in all the public schools to every pupil below the grade of the high-school second year. It also requires the regents of the university, in all their examinations in physiology and hygiene, to propound “a due proportion of questions on the nature of alcoholic drinks, tobacco, and other narcotics.” It further commands that all pupils who can read shall study the subject from text-books, and that to those who cannot read it shall be taught orally. Moreover, it ordains that no text-book of physiology that does not devote a certain proportion of its contents to this subject shall be used in the schools.

Dr. Meehan, while he admits the admirable motives of the promoters of this bill, points out that the legislation on the subject now in force is ample for the purpose, and states his conviction that such legislation is very generally lived up to throughout the State. “Such being the case,” he asks, “why seek to add to an already good and all-sufficient law the ridiculously absurd provisions that young children, unable to read, shall be taught the subject of physiology orally, and that when they are able to read they shall receive four lessons a week for at least ten weeks of each year? The idea of teaching a strictly high-school branch to small, primary-grade children unable to read, and to an extent whereby the time given to it exceeds the amount of time allotted to this subject by our best medical schools! Is not such a proposition absurd on the face of it?” Dr. Meehan certainly takes a rational view of the matter, and it is to be hoped that such an injurious piece of legislation will never be carried into effect.

MINOR PARAGRAPHS.

A JOURNAL OF SOCIAL MEDICINE.

We have received the first number of the Zeitschrift für sociale Medicin, edited by Sanitary Counsellor A. Oldendorff, of Berlin, and published in Leipzig. It is devoted to the interests of physicians as a class, as distinguished from the science they have to study and the art they have to practise. The first number contains an article on Physician and Patient, by Dr. König, of Göttingen; one entitled Why should the Physician’s Calling be Stylized a Profession? by Dr. Oscar Schwartz, of Cologne; one on The Status of the Physician in the United States, by Dr. George H. Rolé, of Baltimore (translated from the English by Dr. Plateczk, of Berlin); and one on The Development of Municipal Homes for Convalescents in Berlin, by Dr. Marzgraft, of that city. In addition, there are literary notes, abstracts, letters, items, etc. Among other things of interest, we find the new fee-bill laid down for the physicians of Germany by His Excellency Dr. Bose, Kultusminister. The new journal makes an excellent appearance and it covers a field to which, so far as we know, no other publication is especially devoted.

A BIT OF ANCIENT MEDICINE.

In an interesting pamphlet on Diabetes Mellitus, Dr. Kallay, of Karlsbad, alludes to the teachings of Susruta, the Indian, two thousand years before the Christian era. It seems that the progress made in medicine since that time has not only materially advanced our conception of the nature of diabetes. Susruta connected the symptoms with the essential malady, which he imputed to the kidneys, and he knew the grave prognosis attaching to the disease. If we have transferred the pathology from the kidneys to the nervous system, have we made any other substantial advance beyond what was known to this old Indian?

THE AMERICAN SURGICAL ASSOCIATION.

Several of the national special societies are holding their meetings at this time, and it is to be hoped that the habit of holding them in early autumn is definitively broken up. The American Surgical Association is to meet in New York next week, and we are confident that the surgeons of New York will look well to the entertainment of their visiting brethren, as well as to their edification by means of clinics and the like. The programme of the meeting is given below.

THE ILLUSTRIOUS BOERHAAVE.

This is the title of an address delivered some months ago by Dr. William T. Lusk, of New York, before the graduating class of the Medical Department of Yale University. It appears in print in the May number of the Popular Science Monthly. It is well to keep the old masters in mind, and it is gratifying to know that a non-medical journal should now and then present medical matters to its readers. Dr. Lusk’s address is full of interest, and may be read profitably by all classes of readers.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending May 21, 1895:

The American Surgical Association.—The annual meeting will be held at the New York Academy of Medicine on May 28th, 29th, and 30th, under the presidency of Dr. Frederic S. Dennis, of New York. The programme includes the following papers: The President’s Address, by Dr. Frederic S. Dennis; A Discussion on the Operation for the Radical Cure of Hernia, by Dr. William T. Bull, of New York, Dr. Charles McBurney, of New York, Dr. Henry H. Mudd, of St. Louis, Dr.
John E. Owens, of Chicago, and Dr. John H. Packard, of Philadelphia; The Results of the Treatment of Hypертrophy of the Prostate Gland by Castration, by Dr. J. William White, of Philadelphia (to be discussed by Dr. L. S. Pilcher, of Brooklyn, Dr. Roswell Park, of Buffalo, and Dr. William S. Halsted, of Baltimore); The Operative Treatment of Cancer in Various Localities, by Dr. F. H. Gerrish, of Portland, Me. (The Female Genital Organs, including the Uterus and the Vulva, by Dr. John Hounans, of Boston; The Lips, the Tongue, the Floor of the Mouth, and the Pharynx, by Dr. P. S. Connor, of Cincinnati; The Breast, by Dr. J. S. Wight, of Brooklyn; The Male Genitals, by Dr. Hunter McGuire, of Richmond, Va.; The Rectum, by Dr. Arpad G. Gerster); Circumstances under which Chloroform is Preferable to Ether as an Anæsthetic, by Dr. G. W. Gay, of Boston; The Influence of Ether upon the Kidneys, by Dr. Robert F. Weir, of New York (to be discussed by Dr. T. F. Prewitt, of St. Louis, Dr. II. B. Wharton, of Philadelphia, Dr. J. D. Rushmore, of Brooklyn, Dr. Robert Abbe, of New York, and Dr. F. E. Lange, of New York); A Discussion on the Restoration of Joint Function after Fracture, by Dr. W. H. Carmalt, of New Haven, Dr. L. A. Sayre, of New York, Dr. N. P. Dandridge, of Cincinnati, Dr. J. B. Roberts, of Philadelphia, Dr. E. H. Bradford, of Boston, and Dr. John Ashburn, Jr., of Philadelphia; The Bacteriological Aspects of Pus and of Suppuration, by Dr. Roswell Park, of Buffalo (to be discussed by Dr. W. S. Halsted, of Baltimore, Dr. L. M. Tiffany, of Baltimore, and Dr. John Parmenter, of Buffalo); Gunshot Wounds of the Heart, by Dr. Chalinda II. Martin, of Mobile; Injuries to the Pneumogastric and Phrenic Nerves, by Dr. Roswell Park, of Buffalo; Dislocation of the Ulnar Nerve at the Elbow, by Dr. II. W. Wharton, of Philadelphia; Ligation of the Innominate Artery, with the Report of a Case, by Dr. II. L. Burrell, of Boston; Immediate Suture of the Gall Duets and the Gall Bladder after Extraction of Stones, with Cases, by Dr. J. W. Elliot, of Boston; A Case of Cholecystostomy, by Dr. S. H. Weeks, of Portland, Me.; Personal Experience with Mad Dogs, by Dr. Basil Norris; Hernia of the Bladder as met with during Operations for Inguinal and Crural Hernia, by Dr. Christian Fenger, of Chicago; The Radical Cure of Hernia by a New Procedure, by Dr. John II. Paekard, of Philadelphia; Ligation of the Spermatic Cord in the Treatment of Hypertrophy of the Prostate, by Dr. J. Ewing Mears, of Philadelphia; Congenital Oesophageal Pouch; Excision; Immediate Suture of the Oesophagus; Recovery, by Dr. S. J. Mixter, of Boston. Clinics will be held at Bellevue Hospital, by Dr. Dennis and the visiting staff; at the Presbyterian Hospital, by Dr. McCosh, Dr. Bridden, Dr. Pilcher, and Dr. Wight; at the New York Hospital, by Dr. Weir, Dr. Bull, Dr. Hartley, Dr. Murray, Dr. Gerster, and Dr. Abbe; at the Roosevelt Hospital, by Dr. McLainey, Dr. Lange, Dr. Fowler, and Dr. Rushmore.

Members of the medical profession are cordially invited to attend the meetings of the association, except when it is in executive session.

The American Gynecological Society.—Among the social accessories of the meeting to be held in Baltimore next week are a dinner to be given on Tuesday by the Gynecological and Obstetrical Society of Baltimore and luncheons to be given on Tuesday and Wednesday by the Baltimore members of the American Gynecological Society.

The Craig Colony for Epileptics has had the sum of one hundred and twenty-five thousand dollars appropriated for its uses during the coming year. Governor Morton has appointed the new board of managers, twelve in number. Four members of the old board, including Dr. Peterson, Dr. Jones, Mr. Culdebock, and Mrs. Wadsworth, are reappointed. Work at the colony will be begun at once for the reception of patients next fall.

The Richmond, Va., Academy of Medicine and Surgery.—At the next meeting, on Tuesday evening, May 28th, Dr. E. C. Levy is to open a discussion on the Treatment of Diphtheria, including Practical Experience with Antitoxin.

St. Joseph's Hospital for Consumptives.—An invited company is to meet Archbishop Corrigan at the hospital, at East One-hundred-and-forty-third Street and Brook Avenue, this (Saturday) afternoon.

The Hospital Graduates' Club held its annual dinner at the Hotel Hungaria on Thursday evening, the 23d inst.

The German Poliklinik held an anniversary celebration at the Liederkranz building on Wednesday evening, the 22d inst.

Change of Address.—Dr. Nathan S. Roberts, to No. 879 Lexington Avenue.

The Death of Dr. Harlan P. Allen, of Columbus, O., we have already recorded as having occurred in New York on May 2d. Dr. Allen was born and educated near Springfield, Mass. He was a student of the late Dr. Thomas A. McElwide, of New York, was graduated at the College of Physicians and Surgeons in 1879, and was afterward an intern at Charity Hospital. He was married in 1882 to Miss Harriet C. Carroll, of Rhinebeck, at which place the internment took place. The Columbus Academy of Medicine has adopted resolutions concerning his death which we publish elsewhere.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending May 16, 1895:

Young, L. L., Assistant Surgeon. Ordered to examination for promotion.

Oscott, F. W., Passed Assistant Surgeon. Detached from the Constellation and ordered to the Enterprise.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Fifteen Days ending May 15, 1895:

White, J. K., Passed Assistant Surgeon. Detailed as recorder of board for physical examination of applicants for appointment in Revenue Cutter Service. May 13, 1895.

Carrington, P. M., Passed Assistant Surgeon. Granted leave of absence for fourteen days. May 4, 1895.

Cohn, J. O., Passed Assistant Surgeon. Granted leave of absence for fourteen days. May 1, 1895.

Society Meetings for the Coming Week:

Monday, May 27th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, May 28th: American Gynecological Society (first day—Baltimore); Association of American Physicians (first day—Washington); American Surgical Association (first day—New York); New York State Medical Association, Fifth District Branch (annual—Brooklyn), New York Dermatological Society; Richmond, Va., Academy of Medicine and Surgery; Buffalo Obstetrical Society.

Wednesday, May 29th: American Surgical Association (second day); American Gynecological Society (second day); Association of American Physicians (second day); Auburn,
DEATHS.—OBITUARIES.—PROCEEDINGS OF SOCIETIES. [N. Y. Med. Jour.]

N. Y., City Medical Association; Medical Societies of the Counties of Monroe (annual—Rochester) and Tompkins (annual), N. Y.; Berkshire, Mass., District Medical Society (Pittsfield).

THURSDAY, May 30th: American Surgical Association (third day); American Gynecological Society (third day); Association of American Physicians (third day).

SATURDAY, June 1st: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society, New York (private); Miller's River, Mass., Medical Society.

Births, Marriages, and Deaths.

Died.

GADBEERY.—In Yazoo City, Miss., on Sunday, May 12th, Dr. W. Y. Gadberry, aged about seventy years.

HENRY.—In New York, on Sunday, May 19th, Dr. Morris H. Henry, aged sixty years.

HESSE.—In New York, on Sunday, May 19th, Dr. Henry J. Hesse, aged forty-two years.

JOYCE.—In New Orleans, on Sunday, May 12th, Dr. P. A. Joyce, aged thirty-four years.

MAXSON.—In Pasadena, Cal., on Friday, May 17th, Dr. O. T. Maxson, of Evanston, Ill., aged seventy-two years.

PERKINS.—In Salem, Mass., on Saturday, May 18th, Dr. George A. Perkins, aged eighty-one years.

THOMPSON.—In Chicago, on Tuesday, May 21st, Dr. Mary Harris Thompson, aged sixty-six years.

TRAVEE.—In Troy, N. Y., on Friday, May 17th, Dr. Richard D. Travee.

OBITUARIES.

MORRIS H. HENRY, M. D., LL. D.

Dr. Henry, whose death took place last Sunday as the result of a chronic illness, was a notable person in the New York profession. His dignity of bearing and the fervor with which he was accustomed to deliver his sentiments in medical meetings will long be remembered, as well as the skill with which, for the few years of its existence, he conducted the American Journal of Ophthalmology and Dermatology. Those who really knew him well were aware that, in addition to dignity and gracefulness, he was possessed of an exceedingly kind heart.

PROCEEDINGS OF SOCIETIES.

THE NEW YORK NEUROLOGICAL SOCIETY.

Meeting of May 7, 1885.

Dr. C. A. Herter in the Chair.

Unocular Blindness.—Dr. J. Arthur Booth presented a case of blindness of one eye without any discoverable lesion in the eye. The special point to which he directed attention was as to whether after a functional blindness had lasted for a year or two the morbid condition might not persist, finally causing congestion and inflammation. The patient, a girl, fourteen years of age, had been perfectly well up to about a year before, at which time she had fallen on the ice and struck her head. Two months after this she had begun to have headache, chiefly frontal. On May 5th she had come to the Manhattan Eye and Ear Hospital because of dimness of vision. Examination had revealed almost total loss of vision in the right eye, without any change in the vessels or disc. While in the hospital she had had two hystero-epileptic attacks. Strabismus had been given freely, but without benefit. Vision in the left eye was 20/20, but could be brought up to 20/10 by glasses. The field was much contracted in all directions. In a moderate fight both pupils were dilated, the right being a little the larger. There was a marked loss of sensation in the right cornea, but no anesthesia of the face, body, or extremities. Colors were readily recognized with the left eye. The knee-jerks were equal, but somewhat exaggerated. The treatment by means of drugs had failed, as had also hypnotism. Various tests had been made to detect any deception on the part of the patient, but the results had been negative.

An Unusual Case of Lead-poisoning.—Dr. William M. Leszynsky presented a man whom he had first seen about ten days before. He had experienced difficulty in making the diagnosis at first, on account of the obscurity of the etiology. The man stated that at the onset, sixteen days before, he had had fever, vomiting, and malaise, but there had been no chill and no bladder or rectal symptoms. He complained of general weakness in the lower extremities. About the same time he first noticed an aching pain in the right shoulder, and two days later the index and the medius dropped, and the pain disappeared. A few days after this the weakness had increased, and when he was first seen by the speaker there was wrist-drop. The left arm and hand were also becoming weak, but there was no pain. Both extremities had felt numb. There was no history of exposure to cold. For five or six years he had been drinking five pints or more of beer daily. Examination showed muscular weakness—paresthesia of the deltoid, the upper portion of the trapezius, and the biceps group—and the extensors were paralyzed, as was also the extensor minimi digiti. There was also extreme tenderness along the course of the nerve trunks, as well as some tenderness of the muscles themselves. With such a history one would suspect lead-poisoning, and there was a slight line upon the gums suspiciously like a lead line, but the man was a cooper by occupation, and at first no history could be obtained of his having come in contact with lead. A provisional diagnosis had been made of alcoholic multiple neuritis beginning in the upper extremities. The urine was then examined, and traces of lead were found in it. There was no albumin or sugar. Inquiry then elicited the fact that he had had occasion to close barrels containing a preparation of white lead. Electrical examination showed absolute loss of faradical irritability in the musculo-spiral on the right side and in the extensors, and diminished faradical excitability in the other muscles that were parietal. Both knee-jerks were active. Ophthalmoscopic examination was negative. This patient had also had tachycardia, the pulse having been about 120 and weak.

Dr. M. Allen Starr said he had recently seen a man who had been in the habit of drinking a large quantity of water from the fountain every morning. It was believed that the water, having remained in the pipe all night, had become impregnated with lead, and that this had given rise to the lead-poisoning. The speaker said he had only seen one case of lead-poisoning in which all the extremities had been affected nearly equally, and where there had been intense pain along
the nerve trunks and muscles. This patient, a painter, had been in the hospital for fourteen months, and all this time had had the typical blue line on his gums.

The Chairman agreed in the diagnosis of lead paralysis in the case reported by Dr. Leszynsky, notwithstanding the unusual tenderness of the nerve trunks and muscles, but he was inclined to think that the fact of the man having been a steady drinker might have had something to do with precipitating these symptoms. Alcoholism certainly precipitated attacks of lead-poisoning. During the past winter he had seen a large number of cases of severe alcoholic neuritis, and had been impressed with the fact that in a certain proportion of these the first symptoms had been pain in the joints and in the muscles about the shoulder.

An Intracranial Gumma.—Dr. C. E. Nammack presented a woman, twenty-four years of age, whom he had first seen two weeks before. For the preceding five months she had had constant headache, with vertigo and vomiting in the early morning. This had been followed by gradual loss of power in the right hand. Two months ago she had found that she was unable to close the left eye. There had been no injury or emotional shock, and there was no history of alcoholism or of venereal disease of any kind. She answered questions slowly, and it was difficult to keep her attention concentrated on any one subject. There was optic neuritis on each side, with beginning choked disc in the left eye. R. V. was $\frac{2}{3}$, and L. V. $\frac{3}{4}$, not improved by glasses. The tongue was farred on the left side only, and taste was diminished on this side. The diagnosis was that of an intracranial gumma situated in the lower part of the pons on the left side. For the past two weeks she had received injections of blue ointment and sixty grains of iodide of potassium three times a day, and already the improvement was remarkable.

Dr. B. Saxon said that it was well to be cautious about making a diagnosis of gumma in a case of this sort solely on the strength of the improvement observed from such treatment. For example, he had seen a man of forty-five years who had had a hemiplegic attack some years before and in whom the administration of a large quantity of iodide of potassium had caused the entire disappearance of all the symptoms for several months. Subsequently this man had had a fatal apoplectic seizure, and the post-mortem had shown a very large glioma. In connection with every neoplasia there was a large amount of exudation, and absorption of this fluid might be responsible for the improvement following the treatment.

Dr. S. Stern said that, if he remembered correctly, Dr. Nammack had himself recently reported a similar case to the society. Within ten days he had seen a boy of sixteen suffering from all the symptoms of well-marked tumor of the cerebellum. When this boy was eight years of age, he had suddenly been seized with symptoms of tumor of the cerebellum, and had been treated for such a tumor by Dr. Seguin. Within two months after the beginning of the antisyphilitic treatment the symptoms had entirely subsided, and the boy had been apparently perfectly well up to six weeks ago, when the eye symptoms had returned. Examination had shown the typical choked disc. Although this boy had not had syphilis, and the family history was exceptionally clear on this point, yet antisyphilitic treatment had caused the disappearance of the symptoms of tumor.

Dr. J. F. Thomas remarks that one could get no idea of the degree of choked disc from the impairment of vision.

Report of a Case of Lead Paralysis, with Special Reference to Cytological Changes in the Nervous System and the Distribution of the Lead.—The Chairman read a paper with this title. The patient was a man, twenty-six years of age, poorly nourished and undersized, who had been admitted into the City Hospital on November 23, 1894, and had died on December 12th. His family history was negative. He had used alcohol moderately, but had never had syphilis. He had been a painter for a number of years. In February, 1894, he had been treated in the same hospital for very severe lead colic associated with double wrist-drop. With the exception of the latter, the symptoms had entirely disappeared during his stay in the hospital, and he had returned to his work. Shortly before his last admission he had begun to have attacks of nausea and abdominal cramps. On admission, he complained of weakness in his arms and legs. Examination showed slight oedema of the lower extremities; the apex beat was diffused and rather weak; the arteries were distinctly atheromatous; the pulse was 80, weak but regular; there was a well-marked blue line on the upper and lower gums; there was well-developed wrist-drop; and there was complete loss of power in the extensors of the wrist on each side, with little power in the flexors. In the biceps of either side the power was unimpaired. There was atrophy of all the muscles below the elbow, and especially of the interosseous. There was no triceps jerk. In the lower extremities there were slight drop-foot and moderate contracture of the calf muscles. The loss of power was rather more marked on the right side. The thigh muscles reacted fairly well to faradism. The knee-jerks were feeble on both sides. No ophthalmoscopic examination was made, but the acuity of central vision was distinctly reduced. The patient was kept in bed and received, by mistake, ten grains, instead of five grains, of iodide of potassium, three times a day. Two days afterward the daily quantity of urine was 1,000 c.c.; it was acid, had a specific gravity of 1.016, and contained half a gramme of albumin to the litre. On December 6th there were 870 c.c. of urine excreted, and it contained half a gramme of albumin to the litre; urea, 14.36 grammes; uric acid, 0.17 gramme; phosphoric acid, 0.20 gramme; sodium chloride, 17 gramme; preformed sulphates, 4.56 grammes; and combined sulphates, 0.20 grammes. The absolutely low amount of urea and relatively and absolutely low amount of uric acid were striking features. On December 7th the patient began to be drowsy during the day, and three days later he was in a mummering delirium, and the pupils were contracted and reacted but little to light. On the 10th, the pupils were of the size of pin-points, the respiration was stertorous, the eyeballs were prominent, the pulse was feeble, and the surface of the body was cold and clammy. Death occurred on December 12th. On the last day 410 c.c. of urine were drawn by catheter. It had a specific gravity of 1.035, and contained albumin and a considerable number of granular and epithelial casts. The ratio of uric acid and urea was 82:7; the chlorides were low, and the sulphate ratio was again exceedingly low. Blood drawn two days before death showed the percentage of urea to be 0.76, which was two to three times the normal amount. At no time had there been convulsive movements.

Dr. Ira Van Ghiso described the result of the post-mortem examination. He said that attention had been paid chiefly to the cytology of the ganglion cells—in other words, to the science of these cells. It was only by such investigations that we could fully understand the changes underlying a great many nervous disorders, and particularly the toxemias, and affections due to over-fatigue of the ganglion cells. By reference to a chart, he showed how complex was the structure of these ganglion cells, as determined by modern methods of research. Lead-poisoning, he said, should be one of the most brilliant fields for this new line of observation, as the process was so slow. At the autopsy, in the case under consideration, several erosions had been found in the brain. The vessels at the base were normal, as were also the cranial nerves. The vis-
The surface of the kidneys was rough and granular, the cortex was very thin, and the topography of the tubules was lost. The submaxillary glands, the thyroid, and the suprarenal capsules showed no significant changes. Dr. Herter had found the epithelium of the secreting tubes in a state of marked granular degeneration, the cells of Hene's loops degenerated and containing hyaline casts, and the cells of the collecting tubes degenerated and proliferated and their lumen filled with degenerated cells and hyaline material. About half the glomeruli were in advanced fatty atrophy; in the remaining glomeruli the capsule was thickened, the capillaries were compressed, and the cells of the tufts were moderately increased. The tufts filled up the capsules.

The peripheral nerves had been hardened in osmic acid and examined, with the following result: In the unlar, about one fibre in every ten was moderately degenerated; in the external peroneal, about one fourth of the fibres were collapsed and degenerated; in the sciatic of the middle of the thigh about one degenerated fibre was found in every ten; in the left external cutaneous there was partial degeneration of one fibre in ten, with more complete degeneration in three fibres in ten; in the right radial at the wrist one fibre in twenty was degenerated; in the left plantar, one in twelve.

Portions of both enlargements of the spinal cord had been hardened in various ways and examined in detail. By applying aniline dyes, fully one third of the ganglion cells showed a form of degeneration which changed the internal composition of the cell, although not its shape. Comparatively few of the cells were completely destroyed. The changes observed were not apparent if the specimens had been hardened in Müller's fluid and stained with carmin. In the specimens examined the chromophilous granules had been broken up and disseminated throughout the ganglion cells. Such changes, he felt, could be considered as entirely independent of the changes observed in connection with rest and fatigue. Some of the cells showed beginning vacuolation, and others an accumulation of pigment. It was now known that the quantity of pigment indicated the age of the cell. Where the degenerative process had gone still further, the cells had been nearly destroyed. These cells had been found equally distributed in the cervical and lumbar enlargements. Fully a third of the ganglion cells showed the mild changes first described as occurring in them.

In the sympathetic system no such changes had been as yet detected. The cerebellum in this case had been found absolutely normal. The motor zones had been particularly examined in the hand region, but, as little work had been done on the normal ganglion cells here, no positive deductions could be made. It was to be remembered that in cases of toxemia there was often a rise of temperature shortly before death, and this might produce some of the changes observed in the nervous system.

The Chairman, continuing, said that the various organs, or portions of them, had been oxidized as thoroughly as possible, and the lead separated from this material on platinum plates. From these plates it had been dissolved with nitric acid, and ultimately converted into a lead chromate, and weighed as such. The spleen contained 0.004 per cent. of lead; the kidney, 0.004 per cent.; the liver, 0.0021 per cent.; the brain, 0.001 per cent.; and the spinal cord, 0.0021 per cent. The lymph nodes of the mesentery gave no lead reaction. The soleus muscles contained 0.0018 per cent.; the lungs, 0.001 per cent.; the heart, a trace; and the blood, contrary to the experience of other writers, 0.0002 per cent. of lead. The brain, spinal cord, and liver contained small amounts of copper also.

The speaker said that the case was of interest on account of the loss of power in the upper and lower extremities and the long time the patient had been exposed to the influence of lead without exhibiting symptoms of lead-poisoning, and also because of the cerebral symptoms shortly before death. The great preponderance of the lesions in the spinal cord over those of the peripheral nerves was, perhaps, the most striking feature of the post-mortem findings. It was to these spinal lesions that the atrophic paralyses must be referred. The changes in the lumbar enlargement were rather more marked than those in the cervical enlargement.

Were the cerebral symptoms to be considered as due to the direct action of the lead on the brain? Three points should here be considered, viz.: 1. The motor areas showed no distinct change in structure. 2. The motor areas contained a small amount of lead. 3. The fact that there were only slight changes in the cortex, which did not exclude the possibility that the cerebral symptoms were due to lead. Two cases had been reported going to show that the cerebral symptoms might be present, even without there being any lead in the brain. A number of facts have support to the theory that these cerebral symptoms were uremic in character. The kidneys in the case reported must have been taxed to their full functional capacity for a considerable time before death. The post-mortem findings indicated that an acute diffuse nephritis had been engorged on a chronic nephritis. The clinical record of the condition of the urine would also seem to support this view, for just before death the elimination of urea had been defective. It might be assumed, therefore, that the retained urea and various leukonecines had been concerned in a large degree in the production of the cerebral symptoms observed shortly before death.

The evidence strongly suggested that the chronic diffuse nephritis in this case was the result of the lead-poisoning. Many observations had certainly shown that this might be a cause of the small, contracted kidney. In this case there was nothing to indicate that there was any true gouty element present. The acute nephritis had possibly been induced by the irritation of the kidneys resulting from the administration of the large doses of iodide of potassium. The spinal cord contained nearly three times as much lead as the brain. There was no significance to be attached to the small quantities of copper found in the brain.

Dr. L. Stilwell said that some years before he had made some extensive experiments with lead on the lower animals. He had noted the vacuolation of the ganglion cells in those animals in which the paralysis had been most marked. Erb, in his paper on lead-poisoning, had maintained that the anatomical changes in the peripheral nerves did not settle the pathology of lead-poisoning—indeed, he went so far as to say that in lead-poisoning there was first of all a functional lesion of the ganglion cells. By "functional" he meant changes so minute as not to be detected by the technique of that time.

The determination of the percentage of lead in the different organs was a very coarse method, and one should be cautious about deductions founded on such determinations. He believed the pathology of lead-poisoning could only be decided when we had found a microchemical test for lead, for we could then demonstrate the presence of lead in the degenerated ganglionic cells. He had devoted considerable time to observations on the kidneys of animals, and had found both chronic and acute nephritis. Half the animals he had experimented on had died of cerebral hemorrhage. The probability that the condition of the kidney was responsible for the cerebral symptoms observed in lead-poisoning had already been urged in a paper by Westphal. It was well known that in acute poliomyelitis of children a certain part of the paralysis was entirely recovered from, and there was no reason to doubt that in
these cases the ganglionic cells of the anterior horn were affected, probably by lesions similar in character to those just described by Dr. Van Gieson.

Dr. Mary Putsam Jacobi thought that the facts brought out had shown that the lead acted, not after being deposited in an organ, but during its circulation through the organ. The nutrition of the ganglionic cells might thus be seriously interfered with, and yet only a small quantity of lead remain in those parts. The frequent association of goit with lead-poisoning was another indication that the lead acted by disturbing the metabolism of the tissues. It was probably in this way that the nephritis was induced, rather than by direct action of the lead on the kidneys. This view would seem to be more in consonance with our knowledge of the comparatively indiff-erent nature of lead.

The Chairman agreed with Dr. Jacobi that the small, granular kidney was produced in cases of lead-poisoning by an indirect influence on the metabolism of the body, resulting in an increased amount of work being thrown on the kidney. He had not been aware that Westphal had stated his belief that lead encephalopathy was due to the condition of the kidneys, although he knew that Oliver had accepted this view for a certain small number of cases. He did not think, however, that any one previously had demonstrated that the blood in these cases did actually contain a certain amount of urea and allied substances.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of April 3, 1895.

The President, Dr. Charles Clifford Barrows, in the Chair.

Goitre treated by Injection.—Dr. William N. Hubbard exhibited a patient in whom he had treated a goitre by injection. Nellie S., fifteen years of age, was anaemic, but well nourished. The thyroid gland had begun to enlarge about two years before she had come to him for treatment, and had increased in size very slowly. In November, 1893, the circumference of the neck had been sixteen inches and a half. Fifteen drops of a solution containing equal parts of tincture of iodine, carbolic acid, glycerin, and water had then been injected into the tumor, and this treatment had been continued two or three times a week until the 1st of the following May. The circumference of the neck at that time had been fifteen inches and a quarter, and the tumor, instead of being rather soft and almost cystic to the touch, had become hard and dense, so that it had been difficult to insert the needle of the hypodermic syringe. Treatment had been discontinued during the summer, and in October, 1894, the circumference of the neck had measured fourteen inches and three quarters, a decrease of half an inch after the treatment had been discontinued. Since then trial had been made of electrolysis. Finding it impossible to properly insert the insulated, sharp-pointed needle ordinarily used for such work on account of the density of the gland, which had seemed as resistant as hard rubber, he had had made, after a model designed by Dr. Walter F. Chappell, a screw-pointed needle. By the use of cocaine this could be partially introduced without pain, but before the insulated portion of the needle could be imbedded beneath the skin the point would lose its hold, on account of the friability of the gland. Owing to the insalution necessary to protect the skin, the needles used for electrolysis were too large to be easily introduced into a hard, tough thyroid gland. A trial had then been made of desiccated sheep’s thyroid, and for several weeks six grains, representing an entire average gland, had been administered three times a day. The results, however, had been entirely negative. At the present time the circumference of the neck was fourteen inches and three quarters, and the improvement had been due to the injections.

Dr. Robert T. Morris said he had recently treated a case of goitre by Poncelet’s method, which consisted in making an incision over the enlarged gland and fastening the skin about its margins without incising the capsule. It had been alleged that, while granulation was going on, absorption of the goitre would take place. He had been rather skeptical about this, but had tried it on one thyroid enlargement nearly as large as the two fists. The thyroid enlargement in this instance had entirely disappeared after the treatment. This was the only case in which he had tried the method. He had expected that there would be a rather broad, dark scar, but the scar had contracted so much as not to be very disfiguring. In the case presented by Dr. Hubbard he suspected that there had been a deep cyst, or else great enlargement of the blood-vessels. It seemed to him that the philosophy of Poncelet’s method of treatment was that absorption resulted from hyperleucocytosis.

Cases of Diphtheria treated with Antitoxine.—The President said he had successfully treated three cases of diphtheria with the antitoxine. On March 22d, at 5 p.m., he had seen a lady of eighteen years, who up to that time had been in good health, except for a sore throat for a few days previously. Her temperature had been 103° and pulse 110, and examination had shown that both the tonsils and the pharyngeal wall were covered with membrane, and the membrane had extended up into the posterior nares. A bacteriological examination had confirmed the diagnosis of true diphtheria. She had been put upon the usual treatment, but had continued to grow worse. On March 25th, the third day after seeing her, her condition had been extremely grave, the membrane having involved the whole pharynx, nasopharynx, and nasal cavities; a foul, acrid discharge had come from the nose; the voice had been reduced to a whisper, and the breathing had been difficult. There had also been some evidence at that time of involvement of the larynx, and the urine had contained a small quantity of albumin. The temperature had been 104°, the pulse 120, and the respirations 30. On March 25th, at 8 a.m., or on the fifth day of the disease, five cubic centimetres of Arousson’s antitoxine, imported by Schering, had been injected by means of a bulb syringe. All other treatment had been then discontinued, except irrigation of the nose with hot boric-acid solution, and the administration of two ounces of brandy in the twenty-four hours, along with food. About twelve hours after the injection the temperature had been 102°, the respirations 30, and the pulse 110. About five cubic centimetres more of the antitoxine had been given. On March 26th, twenty-four hours after the first injection, the breathing had been easier; the temperature had been 100°, the pulse 120, and the respirations 26, and there had seemed to be a slight change in the appearance of the membrane, as if it were about to loosen. At 9 p.m., an eruption like urticaria had appeared over the elbows, hips, knees, and ankles, and this had been accompanied by a good deal of itching and swelling. On the morning of the 27th the pulse had been 100, the temperature 98°8°, the respirations 24, and there had been considerable loose membrane in the throat. The respirations had become easier and the cough less, and it had been possible to inject some fluid through the nose. On the 28th the temperature had been 99°2°, the pulse 100, and the respirations 24, and scarcely any membrane had been found in the throat. She had continued to improve, and about March 31st the membrane had entirely disappeared, and the urine had been free from albumin.

The other children of the family had been sent out of town. On March 30th, one of these, a girl of ten years, had been sent
back to the city with both tonsils, the pharyngeal wall, and the nasal cavities covered with membrane, and with a temperature of 101°, a pulse of 120, and respirations 24. At 11 a.m., chloroform had been given, and ten cubic centimetres of Behring's antitoxin injected. The child had slept until about 7.30 p.m., when she had awakened with a violent delirium, the temperature being 104°, the pulse, 120 and the respirations 30. This had lasted until about 2 a.m., after which she had rested well. At 9 a.m. the temperature had been normal, the pulse 92, and the respirations 20, and the membrane was apparently separating. At 8 a.m. of the 29th, the second day after the injection, the temperature had been normal and the pulse 90, and the throat almost entirely free from membrane. On March 30th the throat had been entirely clear. There had been no albumin in the urine, and no constitutional symptoms except the rise of temperature and the attack of delirium after the injection of the antitoxin.

On March 27th, another sister in the family, nine years of age, had been brought to the city in much the same condition as the last. Ten cubic centimetres of Behring's antitoxin had been injected. At 4 p.m. she had become delirious, with a temperature of 104° and a pulse of 120. About midnight she had fallen asleep and had rested until morning, when the temperature had been 98° and the pulse 96, with the throat in about the same condition. On March 31st the throat had begun to clear off and the membrane had rapidly disappeared, so that on April 2d she had appeared to be entirely well. There had been no unfavorable symptoms except with the first patient, who still had some slight paralysis of the pharyngeal muscles.

Dr. H. S. Horcorouz presented two charts illustrating his first experience with antitoxin. The children were six and eight years of age respectively. The first child had been taken sick on January 7th with symptoms which had not been at first positively diagnostic of diphtheria. On the third or fourth day of the disease he had been forced to the diagnosis of diphtheria, and late at night, with a large aspirating syringe, he had administered the first dose of antitoxin, injecting it into the anterior surface of the throat. At this time the child had shown great depression from the disease. He had watched the pulse closely for two hours after the injection, but had observed no untoward effect from the treatment. It was on account of the injection having been given so late, he thought, that on the 11th the symptoms had all returned, the temperature rising to 103°, and the membrane spreading more rapidly than at first. A second injection had been followed by the same result as at first, and the child had made a good recovery.

On January 21st a second child had been attacked with the disease, and this time the diagnosis had been clear from the beginning. There had been a good deal of acrid discharge from the nose, and a temperature of 103°8, but without much membrane. The antitoxin had been administered at nine o'clock in the evening; and the next morning, although the membrane had been abundant, there had been no constitutional symptoms, and the child had recovered rapidly. On the fourteenth day, in each case, there had been a general erythema, with itching, and in the second case, simultaneous with the eruption, there had been albuminuria. This child had also had some paroxysm.

Dr. J. S. Waterman said that he had had two cases in which he had used antitoxin. His first case, that of a young man of twenty-eight years, had been seen in last December. The membrane had entirely covered the upper air-passages, except the larynx. No antitoxin could be procured until about the fifth day of the disease; then fifteen cubic centimetres of the Giber antitoxin had been injected. On the second day after this a very extensive urticaria had appeared over the whole surface of the body and had lasted about twenty-four hours. Dr. Benson had told him that, in his experience, every case in which the Giber antitoxin had been used had shown this urticaria. He had not noticed in this case any unfavorable influence from the antitoxin.

The next case had been that of a nurse. Ten cubic centimetres of Behring's antitoxin No. 2 had been injected forty-eight hours after the commencement of the attack. The membrane had covered both tonsils and the pillars of the fauces, and there had been considerable constitutional disturbance, with much oedema of the fauces. Within ten hours the oedema had almost entirely subsided, and in forty-eight hours she had appeared to be perfectly well. On the third day after the injection there had been a slight urticaria on the arm. The later development of urticaria seemed to be less common.

The President said that his first case had been as severe an example of diphtheria as he had ever seen, and everything about it had appeared to indicate a fatal termination. There had been a great deal of both local and general infection. The patient had been desperately ill at the time the first injection had been given. The action of the kidneys had been carefully watched, because the French journals had stated that patients treated by the antitoxin had exhibited nephritis much more frequently, and that when it had appeared it had been of a very virulent type. Nothing of the kind had been observed in the cases he had reported. He had used the No. 2 Behring antitoxin—that with the white label.

Dr. R. J. Carlisle asked whether if, in the first case reported by Dr. Houghton, in which the symptoms had returned, the local treatment had been continued.

Dr. Houghton replied that the usual treatment had been adopted from the very beginning, and he had depended very largely on carbonic fumigation and spraying the throat with three-per-cent. pyrozone. There had been no internal treatment.

Dr. L. W. Hubbard suggested that the administration of chloroform in the cases reported by the president might explain the development of the delirium.

The President said that this was, of course, a possible explanation, but the delirium had not appeared for several hours after the patients had completely recovered from the chloroform.

Dr. Hubbard referred to a family in which diphtheria had developed last December. The first child he had been called to see had apparently been suffering from ordinary catarrhal croup, and this had yielded to the steam and other simple remedies. Two days afterward, the baby had been attacked with a membranous sore throat, and a bacteriological diagnosis of diphtheria had been made. Half a bottle of the weaker solution of Behring's antitoxin had been injected at the suggestion of Dr. W. H. Park. At this time there had been stertorous respiration. Five hours later the breathing had been nearly natural, and in twenty-four hours the membrane had nearly disappeared from the throat. Four days afterward, the cook in this family had developed a mild tonsillar diphtheria. She had been given two injections of the first serum made by the Board of Health. The membrane had entirely disappeared in twenty-four hours, and in forty-eight hours she had been going about her work. In neither case had there been any urticaria or any unfavorable symptom.

The President suggested that as the antitoxin solution seemed to contain a certain percentage of trierosol, it was possible that in some instances this might prove toxic to the patient, and so account for the occasional unpleasant results that had been reported.
The Diagnosis of Chronic Joint Disease.—Dr. W. R. Townsend read a paper with this title. (See page 644.)

Dr. Hubbard said that the author of the paper had insisted upon the importance of early diagnosis of chronic joint disease, and that most mistakes in diagnosis were made, not through ignorance, but lack of attention on the part of general practitioners. He would like to again emphasize the statement made in the paper that force was not necessary, but would defeat the purpose of the examination, as it would obscure the reflex muscular spasm. The existence of this spasm could easily be ascertained by careful manipulation after gaining the confidence of the patient.

Pass contraction on one or both sides seemed to the speaker to be an extremely important early symptom of Pott's disease of the lumbar spine. This could often be detected when there was no distinct impairment of the flexibility of the spine. A limp in a child was always an important symptom, and one which should be considered as invariably of sufficient significance to demand a careful examination. This was especially true if the limp was more marked in the morning than later in the day. In knee disease it should be remembered that there might be two forms of disease—chronic synovitis, a disease beginning in the synovial membrane, and disease beginning in one or both of the adjacent bones. If the disease began in the synovial membrane, there would be a rounded, thickened condition of the membrane, with pretty free motion of the joint, and no spasm, except, perhaps, after fatigue. The same remarks applied to disease of the ankle. If the disease began in the synovial membrane, it was not advisable to limit the motion of the joint to the same extent as where the bone was involved; hence, from a therapeutic standpoint, it was a matter of some importance to make the distinctions mentioned.

Dr. Carlisle asked if, in making the diagnosis of early joint disease, atrophy was to be considered, for he could not understand how atrophy could exist except as a result of a neuritis.

Dr. Irving S. Haynes said that it was a fact that there were many joints in which the examiner was in doubt as to the existence of a joint affection until atrophy was detected. If atrophy existed, it should be considered a strong point in favor of the existence of joint disease. Whether the atrophy was due to nerve irritation or to disuse of the joint was a difficult question to decide, but, as it frequently occurred quite early in the disease, it seemed to him that it was probably of nervous origin.

Dr. Hubbard did not think it was due to a neuritis, because the atrophy had existed in cases in which there was no pain, and it might exist before there was any pain in the joint. Neither did he think it came from disuse, because it might appear in children before they had walked about. It seemed to him that by reflex action in the joint a disturbance in nutrition resulted, and, consequently, atrophy. Of course, the atrophy might not be over a quarter or half an inch until the disease had become quite marked. Quite recently he had seen a case of well-marked atrophy due to a fall on the sciatic nerve. It was impossible to make a diagnosis of chronic joint disease from any one symptom; there must be a group of symptoms all pointing in the same direction.

Dr. Townsend said that years ago Brown-Séquard had proved that nerve irritation alone was capable of causing early and rapid atrophy of the muscles; hence it was to be supposed that the first atrophy was due to trophic changes, and not necessarily to a neuritis. In patients who had shown symptoms of the disease for only a few days or weeks, it had not been uncommon to find atrophy on the affected side. If a limb was put in plaster of Paris and immobilized at the joint above, the atrophy would not be anything like that observed in joint disease; hence the atrophy here could not be due simply to disuse.

In reply to a question from Dr. Carlisle as to whether the atrophy was in the spastic muscles, the speaker said that the atrophy was usually to be found in these muscles.

Fracture of the Femur from Muscular Action.—Dr. Irving S. Haynes reported the case of J. W., an athlete, thirty-six years of age, who, while bowling, had attempted to throw a heavy ball, in doing so had lost his equilibrium, and, in endeavoring to regain it, had brought such a strain upon the upper femur as to fracture it in the middle. The line of the fracture had extended slightly obliquely from above and inward, downward, and outward. He had been in unusually robust health, and had been free from any specific disease; hence the manner in which the fracture had been produced was of unusual interest.

Dr. J. W. S. Golley recalled the case of a healthy young man, under thirty years of age, who, while endeavoring to hurl a ten-pound dumb-bell to a considerable distance, had thrown back his right arm so far that it was beyond the control of certain muscles, with the result that the humerus had snapped just below the deltoid insertion. Of course, in this case the weight of the dumb bell had been a decided factor in addition to the muscular action. The fracture had united satisfactorily. No disease of the bone had been found, although the speaker said that when fracture occurred in this way he was usually suspicious of the existence of malignant disease of the bone. It was not uncommon for fractures of bone to occur from very slight causes, such as movements in bed, where there was malignant disease of the bone.

Miscellany.

The Treatment of Secondary Hemorrhage from the Arteries of the Upper Extremity.—The May number of the Medical Chronicle contains an article on this subject by John E. Platt, F. R. C. S., of London, in which the author relates the histories of four cases in which he has been called upon to treat secondary hemorrhage from the arteries of the upper extremity. Three of the cases were examples of secondary hemorrhage from wounds dividing the radial and ulnar arteries and the superficial palmar arch respectively, and the fourth was a case of hemmorrhage from ulceration into the brachial artery. The first case was that of a man with a wound of the wrist dividing the ulnar artery. Secondary hemorrhage had occurred on two occasions. No suppuration had taken place, and the ends of the vessel were readily found and ligated. The second was that of a man with a wound of the superficial palmar arch from which there had twice been secondary hemorrhage. The wound was aseptic and the author found a small puncture in the superficial palmar arch. He applied a ligature on each side of the puncture, and also ligated one of the digital branches which arose close to it. There was no further hemorrhage in either case, and the wounds healed without suppuration.

The other cases were examples of hemorrhage from arteries in sloughy wounds, and the treatment adopted by Mr. Platt was a modification of that usually employed. The first case was that of a young woman who had sustained a wound of the thumb which had been followed by enlargement and suppuration of one of the lymphatic glands lying near the termination of the brachial artery. The abscess was opened and four days later hemorrhage occurred from the cavity. It was not very profuse, but, as it recurred on the following day, the author decided to place the patient under an anaesthetic and explore the cavity. He found that the bleeding came from a small branch of the bra-
MISCELLANY.

Compression

The neighborhood he distal whole return with the divided exposed. For thirteen days after the operation all apparently progressed well, but after that period the hemorrhage returned, and it was necessary to adopt further measures. Plugging the wound would have been useless, for the collateral circulation, if free enough to prevent gangrene of the limb, would have caused a return of the hemorrhage. It was, moreover, impossible to ligate the bleeding point again, for the walls of the vessel were too soft to hold a ligature. After careful consideration the author decided to open up the wound, to trace the artery upward and downward until perfectly healthy parts were reached, to remove the suppuring portion of the vessel and, in order to prevent any further trouble from ligatures, to twist the divided ends. The wound was consequently enlarged and the artery exposed. It was in a sloughy condition, especially in the neighborhood of the distal ligature; this was freed and the whole of the diseased vessel removed. This, says Mr. Platt, was a greater undertaking than he had expected, for he found it necessary to take away four inches of the vessel. The divided ends of the main trunk were twisted, as were also a few small branches which arose from it. From this time the patient made an uninterrupted recovery, the circulation in the distal part of the limb returned almost immediately, and the wound healed completely in about three weeks. The patient at the present time, says Mr. Platt, is perfectly well; the electrified is sound, and there is no interference with the usefulness of the limb. Two enlarged collateral vessels can be felt pulsating near the elbow, one near the external and the other near the internal condyle, but only a very faint pulse is perceptible in the radial artery.

The fourth case was that of a man who had cut his wrist with a piece of glass; the radial artery was punctured, but not completely divided. The bleeding was said to have lasted for five hours, although pressure was applied. The hemorrhage returned on the third following days and he was very anemic; moreover, owing to the great amount of local pressure which had been applied, there was a large sloughy wound just above the wrist. It was impossible, says Mr. Platt, to secure the vessel satisfactorily in the midst of this slough, and he therefore adopted the procedure which had been employed in the preceding case. The vessel was cut down upon just above the wound and divided, and the upper end twisted. Following the vessel downward, a healthy portion was reached in the space between the extensor primi internodi and the extensor secondi internodi pollicis, in which situation it was divided and the lower end twisted. From this time, says the author, the man had no further trouble, although the healing of the wound took several weeks. The length of the vessel was two inches and three quarters, and its walls were in a sloughy condition.

Mr. Platt thinks that this method of treatment is one which may be adopted with advantage in dealing with certain cases of hemorrhage from sloughy arteries, especially in the upper extremity. In such cases, he says, it is useless to temporize; the bleeding is almost certain to recur, and the longer we wait the more extensively will the artery be diseased. Ligation of the main trunk higher up the limb is almost sure to fail, for if the collateral circulation is free enough to prevent gangrene, it will, in all probability, be free enough to cause recurrence of the hemorrhage. Ligation of the softened vessel is difficult and unreliable. The best treatment, says the author, appears to be by ligation or torsion of a healthy portion of the vessel on each side of the bleeding point, and of the two, he gives preference to torsion, as it leaves no foreign body in the wound. The objection to this method, that it opens up the planes of cellular tissue further, is, the author thinks, far outweighed by the advantages. As the wound is freely opened up, the greater part of the sloughy tissue can be removed, proper drainage can be provided, and suitable agents can be applied to excite healthy motion. With regard to the case of the brachial artery, Mr. Platt expresses the opinion that if prompt measures had not been taken in dealing with the suppuring vessel, the case would have ended in amputation.

Inhibitory Procedures in the Treatment of Hiccough.—In the Journal des praticiens for April 29th M. Panza relates the following case: The patient, a young girl, had a good constitution and a nervous temperament. There was no positive family history. At the age of thirteen she had been attacked with nervous symptoms which manifested themselves under the form of more or less convulsive attacks. She showed peculiar characteristics, and was very excitable. The author thought that if he could have made an examination marks of a distinctly hysterical nature would have been found. In February, 1892, the patient took a very hot foot-bath during menstruation, which was immediately arrested, and the patient's general health was very much affected. It produced an almost complete anorexia, which persisted until the 12th of March, when the patient was suddenly taken with an attack of hiccough which was remarkable for its intensity. It occurred from thirty to thirty-five times a minute, and was accompanied by a noise resembling barking. It continued night and day for three days, in spite of the employment of certain procedures commonly used. During the twenty-four hours, however, there were short intervals of rest.

The author was called at once to the patient, and he immediately practised compression of the two phrenic nerves, according to M Leloir's teaching—that is, above the clavicle, between the insertions of the two sterno-cleido-mastoids. The hiccough rapidly became less, and at the end of three minutes it was arrested, only to return, however, after an interval of fifteen minutes. During the two following days revulsives were employed and large doses of chloral and of syrup of ether were taken. The hiccough was then stopped for about twelve hours, when it again made its appearance and persisted with the same violence. The author then decided to resort to nervous compression as follows: 1. Compression of the two phrenic nerves at the neck for ten minutes. The hiccough stopped, but returned in two minutes after suspension of the compression. 2. Compression of the right cubital nerve in the retro-epitrochlear groove for ten minutes. The moderating effect of this procedure was evident, for the frequency and intensity of the hiccough were very sensibly diminished, although it was not completely stopped. 3. Compression of the two phrenic nerves was again employed for ten minutes; the intervals between the attacks became longer, and not more than two or three hiccoughs occurred in a minute. Compression was then suspended, but was replaced afterward by another method, the application of which lasted half an hour. At the end of this time the attack was arrested for about two hours, but returned again at night, when the patient, who was very religious, made a long and fervent prayer asking relief from a condition which rendered her unable to perform her work. Very shortly after-
ward the hicougroh stopped. During the four months that followed this crisis the author saw the patient, and found that menstruation had become re-established, and that the hicougroh had not returned.

In view of all the conditions of this case, says M. Pauzat, the hicougroh seemed to be of an hysterical nature, and it may be that its arrest was due to self-suggestion resulting from the prayer; but it is not his desire to call attention to this case, except from the point of view of the effects produced by the compression of certain nerves. Compression of the phrenic nerves arrested the hicougroh, but only temporarily, and compression of the right cubital was even less efficacious, although it evidently produced a moderating effect. The new method referred to consists in pressing the soft part of the thumb against that of the little finger. By this means the author has always been able to arrest the hicougroh when it is taken in the beginning, and he has recommended the employment of this method to others who have used it with good results. The inhibitory effect is, without doubt, he says, due to compression of the numerous nervous branches in the soft part of the fingers. Pressure of the soft part of the thumb against that of the little finger of the same hand gives rise, in the majority of persons, to a marked tension of the articulations of the first metacarpal with the trapezium and the first phalanx of the thumb. It seems that this tension is not unconnected with the results obtained, and it may thus be understood how pressure of the thumb against the index finger, the middle finger, or the ring finger is less efficacious. In the application of this procedure the following conditions must be scrupulously and carefully carried out: 1. Pressure of the soft part of the thumb against that of the little finger should be energetic, and made simultaneously with both hands. 2. The pressure should be made as soon as the hicougroh begins; once it is established, the procedure may moderate or even arrest it, but it then takes longer to obtain good results.

The Late Dr. Bernard E. Vaughan.—At a stated meeting of the Hospital Graduates' Club held April 23, 1895, the following resolution was adopted:

The Hospital Graduates' Club desires to place upon its records its deep sense of the loss it has sustained in the death of its late member, Dr. Bernard E. Vaughan. From the date of his admission to the club to that of his decease, it had no warmer friend or more loyal supporter than he. He was faithful in his attendance, cordial in his social relations, and able in his scientific work. By his death, the members of the club feel that they have lost a valued friend and the medical profession of the city one of the most promising of the younger men in its ranks. Be it therefore

Resolved, That the sincere sympathy of the club be tendered to his bereaved family, and that this action be entered upon the club records and published in the professional journals of the city.

[Signed.] James E. Newcomb, M.D.,

Resolved, That the profession of medicine has lost one of its most scholarly and worthy representatives, who did much to preserve its fair name and advance its interests.

Resolved, That the community has lost a citizen who, in his professional and social relations was guided by a character of high standard, and whose pure, dignified, and unostentatious life won for him the respect and confidence of all with whom he came in contact.

Resolved, That these resolutions be made a part of the records of the academy, and published in the New York Medical Journal and in the Columbus Medical Journal, and that a copy be transmitted to Mrs. Allen, with the profound sympathy of the members of the academy.

E. J. Wilson, M.D.

[N. R. Coleman, M.D., President.]

W. K. Rogers, M.D.,

The Association of American Physicians will hold its tenth annual meeting in Washington, D.C., on May 30th and 31st, and June 1st, under the presidency of Dr. William Osler, of Baltimore. The programme includes the following papers:

The President's Address, by Dr. William Osler, of Baltimore; Lecithamine Poisoning, by Dr. B. K. Rachford, of Cincinnati; Some Toxicogenic Germs found in Poisonous Foods, by Dr. V. C. Vaughan and Dr. George D. Perkins, of Ann Arbor; The Effects of the Gaseous Products of Decomposition upon the Health of Animals that are Compelled to Respire them, by Dr. A. C. Abbott, of Philadelphia; Renal Affections following Influenza, by Dr. G. Baumgarten, of St. Louis; A Contribution to the Study of Thoracic Tumors, by Dr. William Pepper and Dr. Alfred Stenzel, of Philadelphia; The Etiology of Idiopathic Hypertrophy of the Heart, by Dr. James F. Whitaker, of Cincinnati; The Transmission of Miliary Diastolic Murmurs, by Dr. J. P. C. Giffith, of Philadelphia; The Use of the Differential Stethoscope in the Study of Cardiac Murmurs, by Dr. A. H. Smith, of New York; The Cause of the Exaggeration of Sounds over the Right Upper Chest, both in Health and Disease, by Dr. Charles Cary, of Buffalo; The Preparation of Antitoxine, by Dr. H. C. Ernst, of Jamaica Plain, Mass.; A Case of Madura Foot (Mycetoma Pedis), by Dr. J. G. Adami, of Montreal; Gonorrhoeal Arthritis—Clinical Observations, by Dr. W. P. Northrup, of New York; Hyperthermy up to 66° F., by D. A. Jacobs, of New York; A Comfortable Way of Using Coal in FEVERS, by Dr. F. H. Williams, of Boston; Some Observations on the Spleen and Marrow in Lymphomas, by Dr. J. Guiéras, of Philadelphia; Gout in Michigan, by Dr. George Dock, of Ann Arbor; Displacements of the Liver, by Dr. J. E. Graham, of Toronto; Carcinoma of the Liver with Cirrhosis, by Dr. M. H. Russell, of Philadelphia; Epidemics of Typhoid Fever, Scarlet Fever, and Diphtheria Due to Milk Infection, by Dr. S. C. Basy, of Washington; Forcible Artificial Respiration—the Bell’s Dwyer Apparatus—Cases, Dr. W. P. Northrup, of New York; Carosso's Treatment of Pulmonary Tuberculosis, by Dr. H. C. Ernst, of Jamaica Plain, Mass.; On the Direct Faradization of the Muscous Membranes of the Stomach and the Intestines of Animals (Dogs, Cats, and Rabbits), by Dr. S. J. Metzer, of New York; Two Cases of Fat Necrosis, by Dr. C. G. Stockton, of Buffalo.

The New York State Medical Association.—The Fifth District Branch will hold its eleventh annual meeting in Brooklyn, on Tuesday, the 25th inst. The following papers will be read: The President's Address, by Dr. Austin Flint; Biographical Sketches of the late Dr. S. T. Hubbard (by Dr. S. S. Tupper and Dr. John Shraide), the late Dr. H. Goldbwyte (by Dr. Charles Phelps), and the late Dr. M. T. Field (by Dr.
The Massachusetts Medical Society will hold its one hundred and fourteenth anniversary meeting in Boston, on Tuesday and Wednesday, June 11th and 12th, under the presidency of Dr. Frank K. Paddock, of Pittsfield. The programme includes the following papers: The Shattuck Lecture—The New England Invalid, by Dr. Robert T. Eades, of Jamaica Plain; Modern Views of the Nature and Treatment of Exophthalmic Goitre, by Dr. J. J. Putnam, of Boston; The Home Treatment of Pthisis, by Dr. V. V. Bowditch, of Boston; The Diagnosis of Malaria by Means of Examination of the Blood and the Presence of Laveran's Bacillus, by Dr. Philip Kilroy, of Springfield; The Recent Progress in Genito-urinary Surgery—The Treatment of Enlarged Prostate, by Dr. A. T. Cabot and Dr. F. S. Watson, of Boston; The Epidemiology of Diphtheria and the Use of Antitoxine, by Dr. H. C. Ernst, of Boston; The Pathology of Diphtheria, by Dr. W. T. Councilman, of Boston; The Prophylactic Use of Antitoxine, by Dr. F. G. Morrill, of Boston; The Preparation of Diphtheria Antitoxine, by Dr. J. L. Goodale, of Cambridge; and The Clinical Use of Antitoxine, by Dr. W. H. Park, of New York.

The Indian Territory Medical Association will hold its semi-annual meeting at South McAlster on June 4th and 5th, under the presidency of Dr. M. C. Marsh, of Claremore. The programme includes the following papers: Pneumonia, by Dr. O. Bagby, of Vinita; Headaches, by Dr. R. J. Bond, of Harrah; Pernicious Malarial Fever, by Dr. J. S. Fulton, of Atoka; Diarrhoea, by Dr. P. Donaho, of Afton; The Selection of Climate for Pthisis Pulmonalis, by Dr. B. Fortner, of Vinita; Meningitis, by Dr. E. N. Allen, of McAlester; Chorea, by Dr. J. D. Brael, of Wagoner; Insanity, by Dr. J. T. Wilson, of Sherman, Texas; Traumatism of the Eye, by Dr. J. M. Ball, of St. Louis; Catarracts, by Dr. B. Tiffany, of Kansas City, Mo.; Puerperal Eclampsia, by Dr. W. C. Hall, of Coffeyville, Kansas; Uterine Reflexes, by Dr. G. W. West, of Enid; Retinitis, by Dr. G. R. Buckner, of Enid; Phlebitis, by Dr. G. A. McBrine, of Fort Gibson; The Surgery of Mines and Railways as a Class, by Dr. H. B. Smith, of McAlester; Pott's Disease, by Dr. F. B. Fite, of Muskogee; Fractures, by Dr. W. B. Miller, of Tallihanna; Erysipelas, by Dr. S. C. Tennent, of McAlester; The Surgery of the Gall Bladder, by Dr. J. C. Gumb, of Sherman, Texas; Tetanus, by Dr. B. Hackett, of Fort Smith, Ark.; Urethral Contractions with Prostatic Disturbances, by Dr. M. C. Marsh, of Claremore; and The Modern Surgery of the Bladder, by Dr. Emory Lamphear, of St. Louis.

The Connecticut Medical Society.—The one hundred and third annual meeting was held in Hartford on May 23rd and 24th, under the presidency of Dr. Francis N. Braman. The programme included the following papers: Typhoid Fever, by Dr. Irving W. Lyon, of Hartford; Perforation in Enteric Fever; Its Surgical Treatment, by Dr. Frederick H. Wigg, of Litchfield; Notes of an Epidemic of Typhoid Fever at South Glastonbury, by Dr. Charles G. Rankin; The Treatment of Typhoid Fever at the Hartford Hospi
tal, by Dr. Joseph B. Hall, of Hartford; A Brief History of Serum Therapy, by Dr. Arthur J. Wolff, of Hartford; The Use of Diphtheria Antitoxin in Connecticut, by Dr. Irving W. Lyon, of Hartford; A Report on the Progress of Medicine, by Dr. Elbridge W. Pierce, of Meriden, and Dr. Everett J. McKnight, of Hartford; A Report on the Progress of Surgery, by Dr. Charles C. Godfrey, of Bridgeport, and Dr. L. W. Bacon, Jr., of New Haven; Semi-Centenarian: One Hundred Cases; Comment, by Dr. Frederick M Wilson, of Bridgeport; the President's Address—Medical Sociology, by Dr. Francis N. Braman; Pneumonia and the Treatment of its First Stage by Stimulation, by Dr. William J. Tracey, of Norwalk; Tetanus, by Dr. Edwin B. Lyon, of New Britain; The Modern Management of Natural Labor, by Dr. Henry Fleischner and Dr. Benjamin A. Cheney, of New Haven; Endometritis; Its Surgical Treatment, by Dr. Frederick Schavoir, of Stamford; The Eye and Diseases to which Eye Symptoms Point, by Dr. Arthur N. Alling, of New Haven; The Errors of Refraction found in Four Thousand Eyes, by Dr. Harry S. Miles, of Bridgeport; Cerebral Thrombosis, by Dr. Gustavus Elliot, of New Haven; The Morphine Habit, by Dr. John W. Wright, of Bridgeport; Simple Meningitis, by Dr. Max Mailhouse, of New Haven; Cerebro-sinal Meningitis, by Dr. N. Nickerson, of Meriden; Tubercular Meningitis, by Dr. Stephen J. Maher, of New Haven; A Case of Acute General Military Tuberculosis, of the so-called Typhoid Form—Autopsy, by Dr. James M. Keniston, of Middletown; Modern Improvements in the Treatment of Diseases of the Skin, by Dr. R. A. McDowell, of New Haven; The Localization of Intestinal Obstruction; Illustrated by Three Cases, by Dr. W. S. MacLaren, of Litchfield; Observations on Operations for the Radical Cure of Herinia, with Report of Cases, by Dr. George C. Jarvis, of Hartford; Observations on Appendicitis, with Report of Operations, by Dr. Charles E. Taft, of Hartford; The Diagnosis and Non-operative Treatment of Appendicitis, by Dr. John F. Dowling, of Enfield; Fracture of the Kneepan, by Dr. James K. Mason, of Suffield; Public Hygiene, by Dr. Lacy C. Peckham, of New Haven; A Defense of Public Health Boards, by Dr. Frank W. Wright, of New Haven; The Therapeutic Value of Mountain Forests, by Dr. Charles D. Alton, of Hartford; The Incrivity of Insanity from a Medico-legal Point of View, by Dr. Thomas D. Crotches, of Hartford; A Case of Utero-vesico-vaginal Fistula, with Successful Operation, by Dr. George C. Jarvis, of Hartford.

The New Hampshire Medical Society will hold its one hundred and fourth anniversary meeting in Concord on June 3rd and 4th, under the presidency of Dr. David P. Goodhue, of Springfield. The programme includes the following papers: The Germ considered as a Prime Factor in the Production and Treatment of Disease, by Dr. S. W. Roberts, of Wakefield; Congenital Imbecility, by Dr. Edward French, of Concord; The Physician as a Citizen, by Dr. S. N. Welch, of Sutton; A Report on Surgery, by Dr. J. Franklin Robinson, of Manchester; Electricity in the Hands of the General Practitioner, by Dr. G. H. Saltmarsh, of Lakeport; On Cancer, with Special Reference to Recent Studies as to its Cause and Treatment, by Dr. Gilman D. Frost, of Hanover; Diarrhoea, by Dr. Benjamin Cheever, of Portsmouth; Some of the Uses of Strophanthus, by Dr. W. K. Wadleigh, of Hopkinton; The Bacteriological Diagnosis of Diphtheria, by Dr. Herbert C. Emerson, of Concord; The Serum Treatment of Diphtheria, by Dr. C. P. Frost; The Modern Methods of Treating Diseases of the Nose and Throat, by Dr. O. B. Douglas, of New York; The Physical Basis of Crime, by Dr. John J. Berry, of Portsmouth; Conservatism in Medicine and Surgery, by Dr. Granville P. Conn, of Concord; The President's Address, by Dr. David P. Goodhue.
Original Communications.

SYMPTOMATOLOGY OF CEREBELLAR DISEASE; CLINICAL ANALYSIS OF A HUNDRED CASES, WITH REPORT OF FOUR PERSONAL CASES.*

By WILLIAM C. KRAUSS, M. D.,
BUFFALO, N. Y.,
PROFESSOR OF PATHOLOGY, MEDICAL DEPARTMENT OF NIAGARA UNIVERSITY; NERVOLOGIST TO ERIE COUNTY HOSPITAL, ETC.

The most important addition to our knowledge of cerebellar physiology in recent times is the able monograph of Luciani, published in Florence in 1890. Luciani was first attracted to this field in the summer of 1882, having in that year completely extirpated the cerebellum of a dog and succeeded in keeping the animal alive.

The fact that this was a possibility, and considering the chaotic condition in which cerebellar physiology existed, induced him to make a minute study of the subject, casting aside all theories and hypotheses, and plunging into the very beginning of the work just as if cerebellar physiology had never been thought of.

After eight years of observation and study, he brought his labor to the light of day, and a comparison of his results with the results obtained by other experimenters, and a comparison of these with the symptoms of cerebellar disease, will be the purpose of this paper.

The pioneer of cerebellar physiology depends upon whether the compiler resides in England, Italy, or France. If in England, then Willis is considered the father; if in Italy, then Rolando; and if in France, then Flourens is considered the founder. Willis was undoubtedly the first to lend attention to the cerebellum, although his work was more anatomical than physiological or experimental. Rolando essayed the solution of cerebellar action and experienced upon animals, especially young pigeons, turtles, etc. His technique was faulty, and the animals experimented upon lived but a short time after the removal of the cerebellum. As a result of his experiments he found that slight injuries to, or partial destruction of, the cerebellum influences muscular movements, while complete destruction annihilates the nerve activity, the abolition of which occasions complete paralysis.

Supporting these deductions he cites the clinical cases of Bianchi, Larrey, and Bertini.

In Bianchi's case, abscess of the right lobe of the cerebellum produced paralysis of the right side of the body; in Larrey's case, injury to the right lobe was followed by right hemiplegia; and Bertini's diagnosis of cerebellar disease was based on the uncertain, irregular muscular movements of his patient, resembling the antics of a drunken man.

Although mistaken regarding the presence of paralysis, which is nothing more than a loss of sthenic tone, Rolando proved that the cerebellum exerted some influence over the correlation of muscular forces, and that an insult to one side of the cerebellum was manifested by some disorders on the corresponding side of the body.

Flourens, the brilliant young French experiment, in 1822 addressed to the Royal Academy of Sciences a memoir on cerebellar physiology, which stands to day for all that is accurate and positive regarding cerebellar action from an experimental standpoint. Three of his experiments, which are quoted by all writers on this subject, may not be amiss in this paper:

"I extirpated the cerebellum of a pigeon by successive layers. During the removal of the first layers only slight feebleness and want of harmony in the movements were noticed.

"At the middle layers an almost universal agitation was manifested, but without convulsions; the pigeon executed sudden and disordered movements; hearing and vision remained intact. On the removal of the last layers the faculty of jumping, flying, walking, and maintaining the erect position was lost entirely. Placed on its back, it was not able to recover itself, and became vainly and continually agitated, but it never moved in a firm and definite manner."

The entire removal of the cerebellum, then, in a pigeon results in volition, sensation, and perception remaining intact. The possibility of making general movements persists, but the co-ordination of the movements in regular and definite acts of locomotion is lost.

The second experiment relates to partial removal of the cerebellum in a young cock. The animal immediately lost all stability, all regularity in its movements, and its tottering and bizarre mode of progression reminded one entirely of the gait in alcoholic intoxication.

Four days after, the equilibrium was less disturbed, and the progression was more firm and assured.

Fifteen days after, the equilibrium was completely restored.

Partial destruction of the cerebellum, then, means a temporary loss of muscular co-ordination.

Flourens fell into an error regarding the influence of the cerebellum as crossed instead of direct, each hemisphere exerting its influence over the corresponding half of the body. With this exception, the experimental results of this astute observer remain unchallenged to this day, even though there may be difference of opinion as to his deductions regarding the functions of the cerebellum.

Magendie, another French physiologist, followed closely upon the work of Flourens, and repeated the almost forgotten experiments of Pourfour du Petit—that of cutting the cerebellar peduncles and observing the animal rotate on its longitudinal axis toward the right or left, according to the side on which the peduncle was cut. He also observed what Fodera von Palermo had previously noticed—that injuries to the cerebellum were accompanied by an uncontrollable inclination to lean or even fall backward.

Serres (1826), through faulty experimentation, taught that the action of the cerebellum was crossed; he also observed the tendency of animals to recoil, to incline the head backward, and was the first to call attention to the fact that the cerebellum exerts powerful influence over the ex-
tremities, more particularly the inferior or posterior. This is shown nicely in the experiments upon pigeons, where, after extirpation of the cerebellum, on being thrown into the air they are able to fly, but, on trying to rise from the ground, they are unable to use their feet, because, as Serres says, they are paralyzed.

Gall, the father of phrenology, in the early part of the century taught that the cerebellum was the seat of the sexual desires. This doctrine was combated by Bouillaud (1827), who, studying many clinical cases, asserted that the cerebellum had no connection whatever with the sexual instincts. Bouillaud followed Flourens's experiments, and tried to prove that the cerebellum presided over acts of equilibrium, of station, and of progression.

Andral, in 1833, published the first series of cases of cerebellar disease, and was able to collect ninety-three cases, of which six were under his personal observation. Of these cases, only one, according to Andral, tended to confirm the opinion of physiologists that the cerebellum was the organ that regulated the co-ordination of muscular movements. Longé (1849), in his Anatomy and Physiology of the Nervous System, says, in view of Andral's results, we must be extremely reserved in calling the cerebellum the co-ordinator of voluntary muscular movements. Andral's analysis seems to have precipitated a merry war between the experimental school and the pathological school. The former, following Flourens and Bouillaud, regarded the cerebellum as the organ of co-ordination, while the latter lent it no such functions.

Flint, in his textbook on physiology, page 712, makes a scrutinizing analysis of Andral's cases, and comes to the following very sound conclusions:

"Of Andral's ninety-three cases, eighty-five may be thrown out altogether, leaving but eight; and of these eight cases, five are so imperfectly described and the disorganization of the cerebellum is so restricted that they may also be disregarded. The ninety-three cases are thus reduced to three. Of these three cases, in two it is uncertain whether or not there were deficiency of co-ordinating power, and in one the difficulty in equilibrium or co-ordination was distinctly noted." This criticism does not show that Andral's cases are opposed to the Flourens doctrine.

Following Andral's publication, there seems to have been a lull in the study of cerebellar physiology, for nothing important was published until the year 1860, when Brown-Séquard, in his lectures on the central nervous system, taught that the inco-ordination was not due to the loss of function of the cerebellum, but that it was due to irritation of neighboring parts of the brain carried through the cerebellar peduncles.

Schiff studied carefully the effects of cutting the cerebellar peduncles and was the first to explain one of the elements of cerebellar ataxia—namely, that it was due to incomplete fixation of the vertebral column, the result of paralysis of the vertebral muscles.

Wagner, Dalton, Lusanna, and Renzi, in their experiments on pigeons and birds, added little that was not known of cerebellar physiology, their findings taking more the character of negative rather than positive phenomena.

Dalton, however, found that the greater the extirpation of the cerebellum the more pronounced would be the motor disturbances, and these would disappear, leaving nothing but a certain general muscular weakness. After the disappearance of the inco-ordination, the result of an irritative lesion, there remains the general muscular weakness, the result of the deficiency lesions.

The inco-ordination he believed to be due to the sudden injury to the cerebellum as a whole, rather than the simple loss of a part of its substance.

Renzi asserted that the cerebellum was the seat of memory, while Lasanna set up the hypothesis that the muscle sense resided in the cerebellum.

Other observers, especially Foville and Pinel-Grandchamp, thought that the cerebellum stood in close relation with the posterior white columns, and therefore presided over general sensation.

Leven and Ollivier (1862-'63) rejected the Flourens doctrine, but made the same error as Flourens in thinking the action of the cerebellum crossed instead of direct.

Lays (1864) undertook to resuscitate the Rolandic doctrine, and regarded the muscle weakness following extirpation of the cerebellum not paralytic but asthénic.

Weir Mitchell came practically to the same results obtained by Dalton, Leven Ollivier, and Lays, regarding the weakness following extirpation of the cerebellum, and considered it as one of the great centres of force development for voluntary and perhaps involuntary motion. Its loss leaves finally no functional defect save some inactivity for prolonged muscular activity.

Nottchage in 1870 omitted the theory that to the middle lobe alone belonged the functions commonly ascribed to the cerebellum, and that on lesion of this lobe, directly or indirectly, the symptoms of cerebellar disease exclusively depend.

Ferrier, in his experiments on monkeys, found that when the cerebellum has been totally removed the animals exhibit the most tumultuous disorders of equilibrium, so that station and locomotion are for the time altogether impossible. Gradually these tumultuous disorders subside, so that the animal can sit up, but is so tottering that it falls over on the slightest disturbance or excitement. A persistent feature is the astasia or unsteadiness of the head, trunk, and limbs.

If only one of the lateral lobes is removed the sprawling, ungranted action of the limbs and the astasia are confined to the same side as the lesion.

If the middle lobe is destroyed the symptoms are essentially of the same character as those which follow destruction of the whole organ, but they do not affect one side more than the other and are more pronounced in the head and trunk than in the limbs. These symptoms are less persistent, and in a few months almost entirely disappear. If one of the peduncles is cut the symptoms have the same character as those following destruction of the lateral lobe, and are confined to the limbs on the side of the lesion.

Ferrier concludes that the cerebellum is the organ pre-
siding over the equilibrium of the body or the location of the body in space.

Stefani (1877) regarded the cerebellum as Ferrier the organ of maintaining the equilibrium; Bechterew is also of this opinion, but regards the olivary bodies, the semicircular canals, and the gray matter of the third ventricle as associated with the cerebellum in the performance of this function.

Bianchi succeeded in keeping alive for some time a dog which had the greater part of its cerebellum removed, which showed no sign of inco-ordination, but simply a loss of muscular power.

The results obtained by experimental physiologists previous to Luciani's publication may be summed up as follows:

First, as concerns the negative phenomena, all observers are practically agreed that the cerebellum plays no part whatever over the mind, instinct, intelligence, sensibility, or special senses; these functions belong to the cerebrum alone, and remain unaffected even in the most severe of cerebellar accidents.

That the sexual instinct resides in the cerebellum, as advocated by Gall, has found no supporter, and must be dismissed from further consideration.

The teaching of Rolando, Serres, and others, that paralysis follows cerebellar extirpation must likewise be modified so as to mean loss of tone or simply weakness, which may disappear or persist according to the extent of injury to the cerebellum.

The positive phenomena following complete or partial extirpation are more difficult to enunciate, and any attempt to make generalizations will be met by stern rebukes and demurrers. As Vulpian has aptly said, the problem of the functions of the cerebellum is still far from being definitely solved. However, this much we do know:

1. That lesions of one side of the cerebellum produce symptoms on the corresponding side of the body.
2. That after partial removal of the cerebellum muscular weakness follows, which disappears almost entirely after a lapse of a few months.
3. That after complete removal of the cerebellum in animals the movements of the lower or inferior extremities become tangled, and they refuse to obey the impulses which try to guide their action.
4. That the cerebellum has some function over the regulation of muscular movements, either co-ordinative or compensatory; the weight of opinion seems to favor the former.
5. That lesions of the middle lobe seem to affect both sides of the body, while lesions to the lateral lobes or peduncles affect the corresponding side of the body only.

To Summarize.—The cerebellum, as a center, according to the majority of observers up to 1890, presides over the co-ordination of muscular movements, the effects of which would be to maintain the equilibrium of the body, the guidance of locomotion, and the maintenance of body station.

Luciani's labors in the field of cerebellar physiology deserve the highest encomiums, and his views merit most respectful consideration. It is gratifying to know that which the cerebellum does not do, even if we dispute the things that it does do. Luciani has virtually decided for all time that complete extinction of the cerebellum produces neither partial nor general paralysis of the mind, perception, volition, intuition, muscular movements, or the appetites.

Removal of the cerebellum produces, first, irritative phenomena; secondly, ataxic phenomena. The irritative phenomena follow closely upon the destruction of the cerebellum, and are indicated by such symptoms as opisthotonos and pleurothotonos, rotation round the longitudinal axis, squinting, or deviation of the optic axis. The ataxic phenomenon or cerebellar ataxy is due to three principal conditions—asthenia, atonia, and astasia—due to the loss of a sthenic tone and static influence which the cerebellum normally exerts on the apparatus of movements, and which is the essence of its function. A trophic influence is also exerted by the cerebellum direct on the effrent tracts which spring from it, and indirect on the nutrition of the body.

According to Luciani the cerebellum is an end organ directly or indirectly related to certain peripheral sensory organs, and in direct efferent relationship with certain ganglia of the cerebro spinal axis, and indirectly with the motor apparatus in general. It is functionally homogeneous, each part exercising the functions of the whole, but having special relations to the muscles on the corresponding side of the body.

Now turn from the physiologic-experimental to the clinico-pathological and see how the facts obtained from experiments upon animals harmonize with the symptoms of cerebellar disease.

From 1880 up to the present time, the era of greatest scientific progress that medicine has ever enjoyed, I have been able to collect ninety-seven cases* of cerebellar disease in which the diagnosis was verified by the necropsy.

This does not embrace cases of mental defect or aberration with such lesions as atrophy or absence of the cerebellum, but, with one or two exceptions, only those cases where a diagnosis was surmised intra vitam. To this number I can add three of my own which I will report later on in this paper. These cases have been studied with a view of establishing a syndrome of cerebellar disease based upon the labors of clinicians the world over.

Of these one hundred cases the pathological finding in the cerebellum is as follows: Sarcoma in twenty-two cases, tuberolysis in twenty-two, glioma in eighteen, abscess in ten.

* The cases reported by American observers in this list are those of Eskridge, Journal of Nervous and Mental Disease, 1883, No. 12; Wilkins, Canada Medical and Surgical Journal, 1886, No. 4; Seigni, Journal of Nervous and Mental Disease, 1887, No. 1; Preston, Journal of Nervous and Mental Disease, 1889, No. 4, and 1892, No. 1; Booth, Journal of Nervous and Mental Disease, 1893, No. 3, and 1890, No. 10; Knapp, Journal of Nervous and Mental Disease, 1892, No. 2; Knapp, Intracranial Growths; Percu, Transactions of the American Neurological Association, 1893; Starr, Brain Surgery; Adams and Weir, Annals of Surgery, 1887; Wyman, Medical News, 1890; Ballard, Boston Medical and Surgical Journal, 1890; Angell, Buffalo Medical and Surgical Journal, 1894, No. 9.
tumor (character not specified) in thirteen, cyst in seven, and one case each of softening, embolism, cyst and sarcoma, cancer, gummata, fibroma, and haemorrhage. The procreative faculty of the cerebellum for neoplasms of various kinds is here well illustrated, being particularly partial toward tuberculous and the sarcomata.

The left lobe of the cerebellum was found to be the seat of lesion thirty-two times, the right lobe thirty-two times, the middle lobe seventeen times, both right and left six times, right and middle lobes three times, left and middle lobes twice.

Turning to the clinical manifestations, we find that headache was present in eighty-three cases, absent entirely in six cases, and in twelve cases its presence or absence was not reported.

Vomiting occurred in sixty-nine cases, was absent in nine cases, and not reported in twenty-three cases.

Optic neuritis was found in sixty-six cases, was absent in twelve, and not reported in twenty-three.

Vertigo was present in forty-eight cases, absent in nine, not reported in forty-three.

These four symptoms are generally considered characteristic of intracranial growths, and their frequency in this series of cases shows that whether the tumor resides in the cerebrum or cerebellum the "big four" must ever be regarded as pathognomonic, especially when all of them or even three are present at the same time.

Of the symptoms which we are in the habit of designating distinctly cerebellar, we find that occipital pain and tenderness were present in forty-five cases, doubtful in thirty-nine, absent in eight, and not reported in eight.

Ataxia—and by this I mean the disturbances of motion, especially of the inferior extremities—was noted in fifty-eight cases, absent in nine, and not reported in thirty-two.

Asthenia, or the lack of atletic tone in the muscles as evidenced by weakness, erroneously termed paralysis or paresis, was present in forty-eight cases, absent in fourteen, and not reported in thirty-eight. It would have been interesting to determine whether the muscular asthenia always occurred on the same side as the lesion, as was found in the experiments upon animals, but the clinical histories were very faulty in this particular, and hence no data could be obtained to form any conclusion, although it is generally admitted that such is the case. Convulsions, either partial or general, were present in thirty cases, absent in fourteen, and not reported in fifty-six.

Inclination to go to one side or the other has sometimes served as an index for determining the lobe affected, the rule being that the patient walks toward the side bearing the lesion. Of thirty-five cases where inclination was reported the following results were obtained: Where the lesion was situated in the right lobe six inclined to the right, two to the left, two backward, and one forward. Where the lesion was situated in the left lobe, four inclined to the left, one to the right, and three backward. Where the middle lobe was affected, four inclined to the left, two to the right, and one backward. In eight cases there was no inclination either to the right or left. These results seem to bear out the rule enunciated that the patient moves from the well to the diseased side.

The tendon reflexes were reported normal in ten cases, exaggerated in twelve, and diminished or absent in twelve cases.

Disturbances of the general sensibility were so rarely noted, and the reports so incomplete, that any careful consideration is out of the question.

The symptom astasia, so often quoted by Lavignani, which is the counterpart of the tremors, oscillations, instability of the body in station and motion, has been partly considered under the head of inclination. The tremors which were so often noticed in animals, sometimes compared by writers to the intention tremor of multiple sclerosis, were recorded in only two or three of the one hundred cases collected.

Polyuria and glycosuria were likewise so infrequent, and the cause so hypothetical, that they may be dismissed from the list of primary cerebellar symptoms.

Another important group of symptoms arising chiefly from pressure of the tumor mass upon the floor of the fourth ventricle, producing paralysis of the fifth, sixth, seventh, eighth, ninth, and tenth pairs of cranial nerves, or the blocking up of the vena Galeni and the consequent dilation of the lateral and third ventricles, are only secondary, but concomitant with the primary symptoms help to localize more accurately the seat of the lesion in the cerebellum. The sudden death so often observed in cerebellar disease may be due to the effects of pressure upon the nucleus of the vagus nerves.

Marked changes in the sexual desire, the appetites, or the mental states were not discoverable.

To summarize, the symptoms of cerebellar disease arranged according to their frequency in this series of cases would be headache, vomiting, optic neuritis, vertigo, ataxia, asthenia, occipital pain and tenderness, inclination to turn toward the side of lesion, convulsions, and such secondary symptoms as nuclear paralyses, polyuria and glycosuria, tremors, and sudden death. The negative symptoms would comprise the disorders of the sexual desire, of the mind, of sensation, and the variability of the tendon reflexes.

The following cases* of cerebellar disease have come under my observation. Cases I and II having been previously published, Cases III and IV, seen by me during the past year, are reported here for the first time:

**Case I.** Clinical Diagnosis: Tuberculosis of the Cerebellum; Autopsy: Anatomical Diagnosis: Miliary Tuberculosis, with Infarction of the Cerebellum.—In January, 1888, Willy L., a child of two years, appeared for the first time in the polyclinic for nervous diseases of Professor Mendel and Professor Eulenburg (Berlin), where I had the opportunity of studying the case.

The child was emaciated, thin, pale, and showed, in general, a scrofulous disposition. The father had always been a healthy man. The mother, with the exception of being an alcoholic.

---

had always enjoyed good health. The mother relates the following history:

For some time past the child had been subject to attacks, regular in appearance, occurring every five minutes. During those attacks, which may be regarded as epileptoid, clonic convulsions appear on the right side, particularly involving the right arm; the head is drawn backward and is rigid. During these paroxysms the patient is not in an unconscious condition, nevertheless the mental faculties are somewhat blunted. Movements of the orbits, general convulsions, tonic and clonic, and paresis of the sphincters are wanting. The mother reports that the child complains frequently of headaches, during the night is restless, and sleep is much disturbed. During the past week the child has become quiet and apathetic. The mother also relates that four children have died of similar attacks.

Status Praematur.—The child is in a state of apathy, paying no attention to surrounding objects; is indifferent during the examination. The head is easily moved; no rigidity at the back of the neck. The movements of the eyeballs are normal; the pupils react readily, and show no difference in their size. An examination of the fundus of the eye was not undertaken. The tongue is protruded easily, shows no deviation, shows no appearance of scars either recent or former. The face shows no dissimilarity of the two sides. An examination of the extremitities reveals no paresis or paralysis. The general sensibility is not affected.

The child, in attempting to walk, shows a staggering gait, with a tendency to fall backward, so that it is impossible to make any progress without support. The reflexes are all normal.

An examination of the lungs shows consolidation in both upper lobes, with fine bronchial rales.

The heart sounds are distinct; no murmurs are appreciable. The pulse is not retarded. The examination of the remaining organs gives a negative result.

The diagnosis is that of an affection of the brain—or the cerebellum—based upon the epileptoid convulsions, headaches, staggering gait, dizziness, nocturnal cries, and semi-comatose condition. With reference to the age, constitution, and condition of the lungs it is plausible to infer that the affection is of a tubercular nature.

Ten days later death occurred, and the report of the autopsy is as follows:

The body gracile, emaciated; shows a slight amount of rigor mortis. The cranium is easily removed; no adhesions of the dura. The dura presents nothing of interest. The pin is clear, easily removed; no adhesions to the cortex. Blood-vessels are not engorged.

In attempting to remove the brain from the cranium the left hemisphere of the cerebellum offers resistance, being firmly adherent to the dura. By using some force the adhesions are overcome, but there remains attached to the dura a round, somewhat regular mass of about the size of a hazelnut. The left hemisphere of the cerebellum shows a cavity with irregular walls, corresponding to the tumor attached to the dura.

The cerebrum presents a smooth surface, with no perceptible resistance. Cross sections reveal nothing abnormal. The surface of the cerebellum shows, with the exception of the cavity above referred to, nothing abnormal. A closer examination, however, reveals distinctly the presence of six round, hard tumors, the size varying from a bean to a hazelnut, and a number of smaller ones less distinct in the substance of the cerebellum. Cross sections show the tumors to be distributed in the superior and inferior vermiform processes and the inferior lobes of the right and left hemispheres.

A section of the tumors shows them to be grayish white, of a distinct concentric formation. The centre shows a soft, degenerated caseous mass. The surrounding tissues are edematous.

The examination of the thoracic cavity reveals the pleura pulmonalis covered with numerous yellowish points of about the size of a pin's head. Sections through the lungs reveal in great number the same deposits. The mediastinal glands are swollen and present the same caseous consistency as the tumors in the cerebellum. The heart shows nothing abnormal.

By request of the parents, the examination was limited to the cranial and thoracic cavities.

Anatomical Diagnosis.—Miliary tuberculosis, especially characterized by the formation of tubercular deposits in the cerebellum.

The nodule to which I will pay special attention is a tumor having the size and form of a hazelnut, with a diameter of ten millimetres. It is situated in the inferior-posterior lobe of the right hemisphere, occupying the greater portion of this lobe. A longitudinal section through cerebellum and nodule shows it to extend upward into the region of the corpus dentatum. The grayish coloration of its external layers permits it to be easily separated from the surrounding tissue, while its centre presents two large, opaque caseous masses surrounded by an amorphous structure not possessing the caseous character of the former, being less opaque and of a greater consistence. The central masses are surrounded by a zone having a concentric laminated structure of a light-gray color. The transition into the normal tissues of the cerebellum is not a sharp one, the gray coloration of the external zone of the nodule gradually disappearing. During the section-cutting the nodule shows the following microscopic changes: Gradually diminishing in size, and in the centre several small, opaque, irregular masses appear. Laterally another group of small nodules appear, increasing in size gradually, conglomerating, forming a new nodule laterally and posterior to the one first described. The lobes inferior posterior of the right hemisphere, therefore, possesses two tumors of about equal size; the one situated medially and anteriorly, the other laterally and posteriorly.

Case II. Clinical Diagnosis: Neoplasia of the Right Lobe of Cerebellum; Autopsy; Anatomical Diagnosis: Cyst of Right Lobe of Cerebellum.—For the history of this case and the pleasure of having made the observation I am indebted to my friend Dr. Linus T. McAdam, of Buffalo, N. Y.

Jacob M., aged thirty-six years; height, five feet seven inches; weight, a hundred and seventy pounds; complexion, fair; constitution, robust; well developed. Antecedents, nothing of particular note was elicited; family history good.

Early History.—The patient passed through infancy and adolescence without any serious illness; never contracted syphilis or gonorrhea. Some years ago he suffered a slight attack of insomnia from which, however, he seemed to have fully recovered.

Present Condition.—On October 24, 1892, the patient consulted Dr. McAdam for pain in the back of the head, dizziness, nausea, peculiar revolving sensations in his head, and on standing or while walking an inclination to be drawn backward. So strong were these last sensations that while the patient was in
bed he would be compelled to turn on his right side, his head deep in the pillow, or while working in a stooped position he would suddenly fall backward, and on several occasions received quite severe knocks on his head. Along with these symptoms there coexisted a subnormal temperature, slow pulse, furred tongue, loss of appetite, sallow complexion, discoloration of the conjunctiva, and constipation. The patient was given hepatic stimulants, but without obtaining any alleviation of the distressing symptoms. A few days after this first visit he again consulted his physician, and complained of great thirst and gave a history of polyuria. On examination, the urine was found to contain sugar in abundance, and on measuring the urine it was found that he passed sixty to seventy ounces daily. About this time (November 7, 1892) he experienced considerable difficulty in walking, and was obliged to discontinue all work and remain at home. With assistance he was still able to walk about the house, but his gait was unsteady, staggering, with a marked tendency to fall backward and to the right.

With the exception of the glycosuria and polyuria, which subsided under careful treatment, the remaining symptoms gradually became more and more severe, and a consultation was held. The disease was diagnosed as of cranial origin, but no definite diagnosis was reached. All methods of treatment proving unavailing, and Dr. McAdam being desirous of further counsel, the writer was called to see the case on January 17, 1893, with his family physician.

The patient was found lying upon a couch, complaining of intense occipital pains radiating toward the vertex. On sitting up he felt dizzy, nauseated, and as if his head were being pulled backward. On attempting to walk his gait was staggering, with a desire to fall to the right and backward, and on walking across the room with assistance he would continually veer to the right.

Psycbe.—His mind seemed to be clear and unaffected; sleep, fair.

Motility.—The strength of the muscles of the extremities was diminished, but no more than the inactivity to which he was subjected would warrant; the muscles of the right side were, however, weaker than those of the left.

Tendon Reflexes.—The patellar tendon reflexes were slightly exaggerated. Other superficial and deep reflexes were normal.

Sensation.—There existed no disturbance of the sensory nerves; trophic and vaso-motor disturbances were likewise wanting.

Special Senses.—Unfortunately, the fundus of the eye was not examined, due perhaps to the fact that no ophthalmoscope was at hand. An ophthalmoscopic examination was, however, promised, but failed eventually to be performed. No abnormalities whatever of the special senses were discernible; no loss of sexual power was admitted.

To me it seemed clear that we had to deal with some cerebellar neoplasm, but what its nature or origin I could not say. The characteristic symptoms of cranial tumor—such as intense cranial pain, obstinate vomiting, vertigo, coupled with symptoms which we are wont to denominate cerebellar, as staggering, ataxic gait, inclination to fall backward, occipital tenderness, etc.—warranted the diagnosis arrived at.

Not receiving the desired promise of speedy and certain recovery, the patient sought other advice, and the history of the course of the disease was unfortunately interrupted. On the evening of March 15, Dr. McAdam was hastily called, and arrived in time to see the fatal termination. Inquiry elicited the fact that for two or three weeks previous the patient had been attacked with a slight fever with occasional chills. No convulsions had been noticed at any time.

An autopsy was made on the following day by the writer, assisted by Dr. McAdam, with the following results: The calvarium was rather thick, dura somewhat adherent. The pineal was clear; vessels not markedly injected; Pachionian bodies small and sparse. The convexity of the brain appeared healthy, the convolutions were not flattened, and the fissures were of usual depth. The cerebrum was removed; beginning cephalad, the basilar structures were carefully severed, and, on cutting the right side of the tentorium cerebelli, a clear, amber-colored fluid flowed into the cerebral cavity. The cerebellum was carefully removed, and in the inferior-occipital fossa was found about an ounce to an ounce and a half of amber-colored fluid. On closer examination the right lobe of the cerebellum was found to be flattened, boggy, and considerably smaller than the left lobe. This condition was quickly explained by the presence of a large cavity in the right lobe, the walls of which had collapsed, and the fluid had escaped during the removal of the cerebellum. The entire right lobe appeared to have been undermined, and virtually was nothing more than the walls of the cyst. During the dissection and examination of the cerebellum the undertaker thoughtfully and thoughtlessly sponged the cranial cavity, thus depriving us of any of the cystic fluid for a more careful microscopic examination. It is therefore impossible to say just what the character of the cyst was; whether it was the result of hydatid disease, or of inflammatory or haemorrhagic origin.

Case III. Clinical Diagnosis: Abscess of Left Lobe of Cerebellum; Autopsy; Anatomical Diagnosis: Abscess of Left Lobe of Cerebellum.—S. S., aged forty-two years, kindly referred to me by Dr. C. W. Bourne, of Hamburg, N. Y.; height, five feet five inches; weight, two hundred and eleven pounds; constitution strong, healthy; complexion dark; married and father of children: occupation, salesman; family history shows no trace of any hereditary or constitutional disease.

Early History:—When four years old he had an attack of brain fever and was sick ten days; otherwise he has always been a healthy, robust man, of good habits, moderate in his appetites, ambitions, striving to attain success in everything he undertook.

During the latter part of November, 1893, he slipped on an icy sidewalk and struck on the back of his head. He complained of a numb feeling, but did not experience much pain. It only made his head "feel queer," as he stated, and in a few days he felt no further effects of the fall. The following week he was taken sick with the "grippe," according to his family
physician. He complained of a general malaise, drowsiness, dizziness, pain in the ears, and no出境. He was not confined to his bed, but did not leave the house for two weeks. He returned to his work, but after a week's trial was compelled to abandon it because of the ear trouble, which caused him much pain and dizziness. He experienced a dull, heavy feeling just back of the ears—would tire easily.

About February 1, 1894, he again resumed his work, and soon thereafter had a second fall on an icy sidewalk, striking the back of his head with considerable force. He was stunned for a few moments and complained of much pain about the occiput. After treating the head with liniments and applications for a few days, he was once more able to go on the road. On March 17, 1894, he complained for the first time of a severe headache at the back of the head, and referred to it as "just as if something were trying to burst his head open." The pain was excreting, its greatest intensity being over the left occipital region. Pressure upon the occiput alone would relieve it. About midnight of the same day he began to vomit, apparently on the least exertion, without any warning; no nausea, and the vomited material would be forced from his mouth (projectile vomiting). He was unable to retain anything on his stomach, expelling it immediately, and vomited much watery fluid. The least movement of his head or body would precipitate a spell of vomiting. He complained of much dizziness and vertigo. His gait was staggering, loggy, and he could not rise from the chair alone because of the dizziness and inclination to fall backward. His condition grew gradually worse, and in a few days he was unable to leave his bed. His head would be drawn down into the pillows, and he seemed to have lost the power over the movements of the head. I was summoned to see him in consultation with his family physician on March 29, 1894, and found the status pessans as follows:

A strong, well-nourished, heavily built man of about forty years of age, lying upon a bed with his head drawn backward, the postures of spinal meningitis. On hearing the history of vomiting, localized headache, dizziness, associated with a fall, the backward displacement of the head, I surmised some cerebral disorder. His mind was at times clear—always clear, the family reported; but to me he appeared semi-conscious, would reply tardily to questions put to him, and made considerable effort to make known his wants.

Motility, although impaired somewhat by the long sickness and inability to retain food, was not limited to any special extremity or side; face and tongue were regular on both sides; eyeballs moved lazily; pupils dilated and responded to light. The eyes were dull and heavy. I did not carry an ophthalmoscope with me and so unfortunately could not examine the optic discs.

The tendon and muscular reflexes were exaggerated. Patellar reflexes considerably increased, but no definite ankle-clonus. Apparently no disorders of sensation, although the semi-stupor which he was in may have influenced this examination. He evinced great pain when the head was turned or when the occiput was percussed, but did not feel any other painful sensations.

Pulse was full, regular, uniform, ranging from 78 to 85 per minute.

Temperature, 98.7° F.

Urine contained neither sugar nor albumin and was not increased in quantity.

Bladder and rectum performed their functions normally, and up to March 17, 1894, there was no change in his sexual power.

My suspicions of a cerebral growth were satisfied, and taking into consideration the fall on the occiput, with a history of a preceding attack of gripppe, I ventured the diagnosis of cerebellar abscess. He was in no condition for an operation and palliative measures were resorted to.

A troublesome hiccup set in a few days after my visit, also a paresis of the left arm and leg; both of these symptoms increasing in severity from day to day.

Incontinence of urine, necessitating catheterism, and constipation also made their appearance. He was conscious up to the last, and at intervals would make inquiries about local affairs. On awakening from sleep he would be lighted for a few seconds, then would be calm and composed.

He died on April 11, 1894, and on the following day I was telegraphed for to perform an autopsy.

The head only was examined, as it was deemed unnecessary to make a complete examination.

The scalp was quite thick and bound quite firmly to the skull. No hemorrhages or discolorations could be detected over the occipital region, the result of the previous falls.

The calvaria was somewhat thicker than normal; not adherent to the dura. The sinuses were engorged with venous blood, and the pial vessels were markedly injected, but not abnormally so. The pia was easily removable; there were no opacities, and the Pacchionian bodies were not enlarged.

The cerebro-spinal fluid was clear, amber-colored, and of the usual quantity. The cerebrum was carefully removed from the fossa, and on cutting the tentorium and attempting to roll out the cerebellum so as to cut the spinal cord, a thick, creamy fluid burst through the lateral walls of the left cerebellar hemisphere.

The brain was carefully placed on a platter and sections cut through the cerebrum, longitudinally and transversely. A small quantity of fluid was found in the lateral ventricles; no hemorrhages, no inflammatory conditions, and no diseased condition of the cerebral arteries could be detected. The cerebellum, however, was of more interest.

The right side was firm and elastic to the touch, while the left hemisphere was boggy, and on the slightest pressure a thick, creamy pus exuded from a large longitudinal opening in the lateral wall of the lateral lobe. The opening was perhaps one inch in length, and opened into an irregular cavity about the size of a small hen's egg. The walls of the abscess cavity were congested, irregular, and had a reddish-haemorrhagic appearance indicative of a former congestion or capillary hemorrhage. The pus was not examined bacteriologically and its bacterial contents can not therefore be given.

**Fig. 3. Case III.**

1. abscess, denoted by the dotted line; 2, opening of the abscess; 3, trigeminal nerve; 4, pons.
Analyzing this case briefly, we find present the three cardinal symptoms of brain disease: localized headache of the bursting variety, dizziness, and cerebral vomiting—i.e., vomiting without nausea, without warning, and forced from the mouth (projectile). The other cardinal symptom of brain disease—tumor, choked disc, or optic neuritis—was unfortunately not sought for, and must therefore be left out of consideration.

The history of two severe falls upon the occiput, with symptoms of pain and numbness for a few days following, the staggering gait, tenderness and rigidity of the neck muscles, with head drawn backward, pointed to some cerebellar affection. The gradual implication of the left side of the body, semiparesis, consciousness up to the end, and the behavior of the reflexes, strengthened the theory of cerebellar disease. The diagnosis of abscess was made upon the theory that as, prior to the falls, he had been sick with an infectious disease, and as septic processes are liable to be lighted up consequent to such injury, the idea of abscess seemed to me both plausible and possible. Trauma is recognized as one of the most prolific etiological factors of brain abscess, the shock seeming to tear and bruise the tissues directly under the seat of injury, causing hemorrhage, inflammation, disintegration, and finally necrosis of the nerve elements. The presence of pyogenic bacteria in the system, and the cordial invitation which such a focus of softening and dissolution extends to the gallant germs, results in the speedy formation of a suppurating abscess.

Case IV. Clinical Diagnosis: Tuberculosis; or else Abscess of Cerebellum.—L. L., female, unmarried, aged twenty-three years; height, five feet four inches and a half; weight, one hundred and twenty-four pounds; complexion, dark; constitution, delicate.

Antecedents.—Father and mother both living and healthy, aged forty-six and thirty-eight years respectively; three brothers and two sisters likewise healthy.

Paternal grandparents: Grandfather living and healthy, aged seventy-four; grandmother died of typhoid fever, aged sixty-one years.

Maternal grandparents: Grandfather died of paralysis, aged seventy-two; grandmother died of diarrhöea of the liver, aged fifty-seven years.

No history of tuberculosis among near or distant relatives could be elicited.

Early History.—When a child she had measles, chicken-pox, diptheria, scarlet fever, and malarial fever. When nine years of age she fell over suddenly and injured her back, a large bunch appearing over the lumbar region a little to the right of the spinous processes. She was unconscious for twenty-four hours, and suffered great pain. Curvature of the spine developed, and for a year she was unable to walk about. Was vaccinated when fourteen years old, and immediately her back grew worse, the deformity increasing until a right scoliosis was well marked. She wore braces for some time and improved in general health, so that the spinal irregularity was scarcely noticeable. When nineteen years of age she had a severe attack of pneumonia, and every winter since then has had heavy colds with cough, expectoration, symptoms of fever, and periods of extreme weakness. At the same time she began to notice a dull, heavy ache over the occiput extending down the spine, accompanied with vomiting spells and dizziness; was taken with fever which ended suddenly, and began to improve and increase in weight (winter of 1891). The following winter she again had the occipital headaches, but without vomiting or dizziness. In January and February, 1893, the same familiar headaches reappeared and as quickly subsided, leaving her in comparatively good health for the remainder of that year. On July 4, 1893, she weighed one hundred and thirty-six pounds, the week before Christmas of 1893 she was taken with a slight attack of the then prevalent grippe.

Her present sickness she dates back to January 1, 1894, when, without any warning whatever, she would vomit forcibly a watery, stringy fluid. She narrates that while going through the figures of a quadrille one evening in January, 1894, a convulsive act of vomiting overtook her on the dancing floor. Headaches, confined mostly to the occipital region and extending down the spine to the middle of the back, made their appearance, sharp and piercing at first, then would gradually wear away. Along with the headaches she would have dizzy, staggering spells, and on rising from a chair would feel falling backward. On walking she would constantly pitch to the left side, and would put out her left hand to save herself. On several occasions her left knee and leg would give way, precipitating her to the ground. Accompanying these symptoms she would experience, two or three times daily, a feeling of extreme heat come over her which would be followed by hot chills. Her face would redden, flush, perspiration would break out, and in a short time she would complain of the room being too cold. The headaches, vomiting, and vertigo growing more intense, she was referred to me by Dr. C. C. Frederick on April 21, 1894, for special treatment.

Status Present.—April 21, 1894, I found her a fairly well developed, bright, intelligent, and active girl, with no indications of any mental disturbance.

Head.—Not painful on percussion except over the occiput, and when pressure is exerted over the left occipital region she complains of severe pain, just as if something were crushing her head, or as if the back of her head were falling out. Her hair, which is long and beautiful, is coming out rapidly, and many gray hairs have appeared within the past year. Her face when she entered the office was cold, pale, and anemic, and before leaving it was hot, flushed, and feverish.

Eyes.—No disturbances of motility, but when they are fixed to the right or left she experiences a pain over the occiput. Pupils react to light and accommodation, and are dilated. No nystagmus and no appearance of any optic neuritis (choked disc).

Ears.—A buzzing noise has been heard at times, and she bas sometimes experienced an itchy feeling in both ears. No deafness.

Nose and Mouth.—Nothing abnormal about the sense of smell or taste. The tongue protrudes without deviation and is not coated.

Appetite poor.

Motility.—A staggering, uncertain gait is manifest, and her mother reports an inclination of wheeling to the left, and has repeatedly chided her for the unsteady like way in which she walks. Standing with her eyes closed, she tends to fall backward. Inco-ordination of the hands or legs can not be detected.

Right-hand grip, as measured with the dynamometer, 50; left, 48. Muscles are rather flabby.

Sensation.—No distinct abnormalities of sensation can be detected.

Reflexes.—Somewhat, though slightly, increased, especially the patellar tendon; no ankle-clonus. Superficial reflexes not exaggerated.

Internal Organs.—Heart and lungs appear undisturbed. Pulse, 80, regular and uniform; temperature, 37.8° C.

Bowels regular. Urine, high specific gravity; no albumin, but shows presence of sugar.

General Symptoms.—She sleeps very poorly because of the pulsation in her head. When she turns over she feels as if something heavy had turned over in her head with a thump.
Menses irregular; flows profusely for eight or nine days. She has lost much in weight since January 1, 1894, her clothes all becoming too loose and baggy. Her hands and feet are generally very cold and covered with cold perspiration, and yet her face will be hot and flushed.

The severe headaches, projectile vomiting, and vertigo, along with occipital pain and tenderness, inclination to fall backward, and of veering to the left, the sudden giving way of the left leg, ataxic gait, with general sensitivity and reflexes but little if at all disturbed, indicated some cerebellar growth, seated in all probability in the left lobe. The slow growth, previous history of the patient, and fever phenomena suggested to me the presence of a tubercular nodule undergoing softening and disintegration.

Without disclosing my diagnosis to the patient or her parents, I put her on a palliative and constructive treatment, which seemed to relieve and benefit her for about five weeks. The symptoms became suddenly more severe, and feeling pretty confident that if an operation could be secured an abscess cavity would be found, I entreated the parents to yield to what seemed the only procedure that would offer any hope of saving the daughter's life. Consent was obtained provided the operation would not be performed unless it was reasonably certain that it would bring relief, and the patient was transferred to the Sisters of Charity Hospital. A thorough examination made June 19, 1894, revealed the following additional facts:

She feels as if her chin were being elevated and the head drawn backward. At night the head digs deep into the pillows. Pressure over the occiput provokes a feeling of nausea.

'Sensation.—Some slight disturbances of sensation have presented themselves, as delayed sensation over the forehead and areas of hyperesthesia about the face and hands, which perhaps arise from the state of mind occasioned by her surroundings. Her eyes were tested to-day by Dr. A. A. Hubbell, whose report is here appended:

"R. and L. hyperesthesia. 0-75 D.; no optic neuritis; esophoria, 3°; abduction, 8°; adduction, 25°, one trial, which can be brought up to 40° or 45°. There is nothing here to account for symptoms."

Measurements of the arms and legs give the following results:

<table>

Strength of hands: Right, 40; left, 40. The strength of the legs, as measured with the pedo-dynamometer, shows: Right leg, 30; left, 36.

The temperature has ranged from 38-5° C. to 40° C. Pulse, 70 to 85 a minute. Urine shows now no trace of sugar.

The surgeon in charge, Dr. H. Mynter, desired to keep her in the hospital for a few days before operating and to watch her closely, so that in case she should fail rapidly an operation could be performed at once. To our surprise, instead of failing she seemed to improve, the vomiting was less frequent, the head less painful, appetite improved, the fever symptoms were less marked, and her general health was gaining. Encouraged by this change in her symptoms, the parents removed her to their home and all thoughts of any operation are now relegated to dreamland.

My diagnosis and mode of relief, so nicely planned and specified, have provoked some twitting remarks, but nevertheless I am positive that the diagnosis was correct, and the operation would have sustained me.

I have seen the patient several times since she left the hospital, and still find left occipital tenderness, unsteadiness of gait, vomiting and vertigo. Her general physical condition is below par; she is pale, anemic, and still complains of feelings of heat and cold.

I have at no time observed any manifestation of hysteria or any type of malarial fever, and am confident that her cerebellum harbors a latent tubercular nodule.

TRAUMATIC CYST OF THE BRAIN
FROM AN INJURY RECEIVED TWENTY—FIVE YEARS BEFORE.

By J. T. Eskridge, M. D.,
Professor of Nervous and Mental Diseases
IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO;
Neurologist to the Arapahoe County and St. Luke's Hospitals:

And F. F. McNaught, M. D.,
Surgeon to the Union Pacific and Denver and Gulf Railroad Company.

HISTORY AND NEUROLOGICAL REPORT BY DR. ESKRIDGE.

Mr. L. L. S., thirty-five years of age, born in Tennessee; married; white; tobacconist by occupation; has lived in Colorado eleven years. Consumption in relatives of both father and mother. Mother suffers from migraine. There are no other points of importance in the family history. The patient's health in childhood was good, with the exception of migrainous headaches, which began when the boy was three or four years of age, and from which he suffered two or three attacks each month. When he was nine years old he was kicked on the head by a colt only four months old, the hoof striking about an inch and a half above the external third of the left supraorbital ridge and fracturing the skull. He was rendered unconscious by the blow, and considerable brain substance was lost through the wound. The depressed bone was not elevated, but after the physician had passed his finger into the brain he stitched the soft parts together. The boy regained apparent consciousness in about twenty minutes, and within a month or two after the injury he was able to be out and play with the children of the neighborhood, showing no obtrusive evidence of mental impairment. While to the parents there seemed to be no mental disturbance after the first shock of the blow had passed away, yet, in fact, consciousness was blurred for some time. The first thing that the patient remembers after the accident was his going to school, which occurred eleven months subsequent to the receipt of the injury. He remembers distinctly playing with the colt before he was kicked, and the name of the boy who was with him at the time, but does not remember being injured, nor can he recall the slightest incident of his experience during the first eleven months that elapsed subsequent to the injury, although for nine months of this time he was to all appearances in a normal mental condition. His health continued good up to his ninetenth year, and even the headaches from which he had suffered be-
fore the head injury rarely occurred. At his nineteenth year, after exposure to the sun's rays, he began to complain of constant headache, and suffered from occasional attacks of unconsciousness, during which he could not talk, but simply made a gurgling noise in the throat. On one occasion he had a series of these, each lasting for a few minutes and recurring about every hour for a number of days, but they gradually lessened in frequency, until the end of the tenth or twelfth day, when they ceased. After the cessation of these spells he was apparently as well as before they occurred. Between each attack of this series, in the early part of it, he lay in a semiconscious condition, apparently taking no notice of anything, simply eating and drinking when food and liquids were placed in his mouth. As the attacks became less frequent, consciousness returned during the intervals. Since his nineteenth year he has had three general convulsive seizures on three different occasions, before the occurrence of the convulsions for which Dr. McNaught was called to see him. The three convulsions referred to were brought on by indulgence in alcohol and exposure to the sun's rays.

The patient's mental condition seemed to be unimpaired up to about his twenty-fifth year, when the first convolution precipitated by alcoholic indulgence occurred. From that time on memory and self-control seemed weakened, and he became more irritable and dependent.

On Monday, September 6, 1894, after indulging in alcohol, he had a severe convolution and lay unconscious for thirty-six hours. On the evening of the next day he had two convulsions which were general and quite severe. On the third day he had eleven general convulsions, and on the fourth, fifteen, all of which were severe, and during the intervals between none of them did he show any evidence of returning consciousness. After the convulsions ceased, on Thursday, September 9, 1894, he remained in a semiconscious condition until the following Sunday night, when I saw him, in consultation with Dr. McNaught. At that time, if left alone, he lay in a stupid, drowsy condition; if roused, he would answer a question, but his answers were unreliable. On account of his mental condition the examination of the special senses and general sensory phenomena was unsatisfactory. The knee jerks were found increased, the left slightly more than the right; ankle clonus was absent; tendon Achillis slight; plantar reflexes were present, but slight; cremaster and abdominal reflexes were absent; the deep reflexes of the arms were about normal; dynamometer—right, 140; left, 120. There was no paresis or paralysis of any muscles, nor involvement of any of the cranial nerves. The pupils were normal in size, and responded readily to light and accommodation. Vision seemed to be perfect. The ophthalmoscope showed no distinct change in the retina or optic nerves, although the left disc was apparently hyperemic, and the edges of the nerve were a little whiter than normal. Hearing—watch—right, 5; left, 1; the tuning fork was heard better in the right ear. Temperature was 99° F.; pulse, 80; respiration, 20. Constant headache, localized in the left frontal region, was complained of. Mental hebephrenia was well marked. The presence of the depressed fracture of the frontal bone, together with the localized headache, was the only evidence of focal brain lesion. It seemed to us that the most probable lesion to give rise to the symptoms in the present case was a localized meningitis caused by depression of bone. An exploratory operation was advised, and readily acquiesced in by the family.

**Operation and Subsequent History. By Dr. McNaught.**

The patient was transferred to St. Luke's Hospital on September 12, 1894, the day preceding the operation. The hair was removed from the head and face and the parts thoroughly cleansed with antiseptic soap, and the head incased in bichloride dressings, in which the parts remained until just immediately before the operation, when they were again cleansed with an antiseptic solution and washed with ether. A semilunar flap was made, which included all the old cuticular tissue and extended two inches posterior to the original fracture. The flap was turned backward and an effort made to separate the pericranium, but this was found to be impossible over the seat of the old fracture, as the pericranium was continuous with the fibrous membrane which extended into the brain cavity. The bone was found depressed, and covering the opening in the bone was a dense membrane composed of fibrous tissue. This was also continuous with the pericranium and with the fibrous membrane that extended into the brain along with the depressed bone. On dissecting the parts, it was found that at the time of the injury a fracture had occurred in the bone, triangular in shape, about an inch in its longest diameter and three quarters of an inch at its base, with the apex of the triangular piece of bone depressed deep into the brain substance, almost at right angles to the skull. Connected with the depressed bone a cyst was apparent, and the trophine was applied about an inch posterior to the base of the fracture and a button of normal bone removed. By the use of the bone forceps the depressed bone was loosened, but on attempting to remove it a distinct convolution was observed, involving all the muscles of the extremities as well as of the face. After removing the spicula of bone a large cyst was discovered, occupying a space in the frontal lobe about two inches and a half in its longest diameter by one and a half to two inches in its transverse. The contents of the cyst were a straw-colored watery fluid, and the walls of the cyst were firm and fibrous in nature. After evacuating the contents of the cyst the inner surface of the sac was scarified and the cavity packed with iodofom gaue, the scalp returned to its normal position and sutured, sufficient room being left, however, to permit of repacking the cyst cavity. After dressing the wound the patient was placed in bed and rapidly reacted, very little shock being apparent. The temperature did not rise above 100° F., and usually remained at about 99° F. At the end of four days the dressing and packing were removed, when it was found that the cavity of the cyst had been reduced to about one half of its original size. The cavity was again repacked and the wound redressed, and at the end of eight days from the operation it was found that the cavity was practically obliterated. The patient's mental condition rapidly improved within two or three days after the operation, and at the end of two weeks he was able to leave the hospital feeling quite well.

On April 6, 1895, the patient reported that he felt quite well, was free from headache, and his memory and powers of mental concentration had much improved. During the latter part of January of the present year, after indulging in two or three drinks of whiskey one day, he awoke next morning feeling languid and suffering some from headache; found the tongue bitten, and his pillow bloody. Four days later, after taking four drinks of beer, he had a similar experience. Since then he has not indulged in alcohol, and has been free from convulsions and discomfort in the head.

The convulsions of recent occurrence evidently have been less severe than those he had before the operation, as he states that formerly a fit left him in a confused mental condition for several hours.

The recurrence of the convulsions in this case after the removal of the cyst teaches us that, after getting rid of the original cause of epileptic seizures, the fits may recur from trivial excitants. The presence of a foreign body, as a
cyst or a tumor, in the brain for a length of time gives rise to structural changes in the surrounding brain substance, and probably to a greater or less extent interferes with the normal functioning power of the cells of the entire brain, so that an unstable and weakened condition of the brain remains for an indefinite period after the removal of the offending agent. Besides, when the growth is in contact with the membranes a thickened and inflamed state of the meninges is left behind for some time. In cases of convulsions due to the presence in the brain of a tumor, cyst, or depressed bone, after the removal of the cause of the original convolution, the same precautions should be employed in avoiding all the ordinary exciting causes of the fits for some time after the operation as before it. Further, it is good practice to place such cases upon one of the bromides for several months to a year or two after the removal of the growth, in order to lessen the abnormal irritability of the brain cells. As alcohol, both before the operation and after it, has been the apparent exciting cause of all the convulsive seizures, it must be entirely proscribed in this case.

UNINTENTIONAL NEGLECT IN THE TREATMENT OF SURGICAL DISEASES.*

By Howard Lilienthal, M.D.,
Clinical Lecturer on Surgery in the New York Polyclinic; Assistant Attending Surgeon to Mount Sinai Hospital, New York.

There is no reproach so severe in the eyes of a physician as the reproach of neglect; and indeed the man who is careless of the welfare of those intrusted to his keeping, who can lightly let slip any opportunity which might change favorably the course of disease, does not deserve fellowship in the noble brotherhood of medicine. Yet one of the commonest faults of the physician is a kind of unwitting neglect where action is delayed in cases of unrecognized or dimly suspected gravity. Such dangerous delays occur in the practice of all the branches of medicine, but I shall speak here only of a few of the diseases known as surgical, drawing my conclusions and citing instances entirely from personal experience.

First, then, cancer. This hideous malady, no matter where situated, is always a surgical disease. It is not in every case amenable to operation, but as yet no medicine has been of the slightest avail. On the other hand, complete timely removal of the diseased area is known to give promise of freedom from relapse. Yet the patient rarely consults the surgeon until systemic poisoning has occurred, the intervening time having been largely taken up with worse than useless attempts to cure the trouble with salves, internal medication, or by means of faith, the latter form of therapeutics doing, perhaps, less harm and giving more mental comfort than either of the others. This is all too frequently the fault of the physician. I confess it makes my blood boil to hear, as I often must, the diagnosis of malignancy deferred because there is "no cachexia."

It seems to me very like waiting for uræmic convulsions or coma to establish the diagnosis of renal trouble.

Take, for example, cancer of the tongue. If one sees the case early, there is probably a small lump or even a flat ulceration which gives no pain. No lymph nodes are enlarged and the patient feels uneasy simply because he knows that the sore exists. Yet, if antisyphilitic dosing for a week and the removal of sharp or irritating teeth are not at once followed by noticeable improvement, the case is one for excision with a wide margin of apparently healthy tissue. The freezing microtome will enable a diagnosis to be made in a very few moments, when more extensive operation at the same sitting may, if necessary, be undertaken. It has been my lot to see cancer of the tongue treated nearly invariably too long for syphilis. Even if there is a history of this disease, it does not forbid the diagnosis of cancer, but makes it more probable. Cancer is prone to develop on a leucoplakial tongue.

Case I.—C. G., a gentleman forty-two years old, came to me about a year ago with a nasty, foul-smelling sore on the left side of his tongue near the tip. It was hard and was sloughing in the middle. An indurated lymph node could be plainly felt near the left extremity of the hyoid bone. A sharp and jagged tooth seemed to be the irritating cause of the sore. For over seven months an energetic physician had treated this man with mercurial infusions and iodide of potassium. He still insisted that because the man had said that he once had had a chance the sore on the tongue must be syphilitic. So sure was he of his diagnosis that he had not even advised the extraction of the sharp tooth. This was done soon after I saw him, and I then removed the left half of the tongue, together with the enlarged glands of the neck. The disease was, however, so extensive that a relapse occurred in the neck within three months, and in half a year the man was dead. A common enough history, but it teaches a lesson which seems hard to learn, for all its simplicity.

Cancer of the breast is a disease which seems to cause more than its share of culpability among medical men. If there is one ailment above another where an early working diagnosis is easily made it is this one. Yet, how horribly often do we hear men give the advice to wait for this or that symptom, in the meantime quieting the poor patient with plaster and salves! It is bad enough to listen to doubts as to malignancy because the nipple is not retracted, or because there is no discharge or no immobility of the tumor; but when an apparently intelligent practitioner doubts the existence of a cancer until the amput is invaded, what shall we say? Every recent graduate ought to know better than to look for such a sign. It is almost or quite as bad as to wait for a board of health report before instituting treatment in a malignant case of diphtheria.

Case II.—A stout woman, Mrs. C., thirty-eight years old, consulted me some months ago regarding a lump in her right breast. It had first been noticed a year before, and from that time she had been constantly under the eye of her physician. The treatment had been by medicines, lotions, etc. Finally, becoming a little suspicious, she came from her southern home to New York for an opinion. I found a tumor as big as a large egg adherent to skin and muscle, with numerous enlarged lymph nodes in both axillae. The woman was slightly corpulent and there was not a sign of cachexia. I amputated the left breast,
with the axillary contents and the pectoral fascia, also removing a lymph node from the left armpit. It was cancerous. The friends of the patient, learning of the bad prognosis, advised against further operation and took her home to die.

The progress of this case had been slow, and I am sure its outcome would have been very different had the physician observed his patient for a month instead of for a year. Instead of insisting on an exploratory incision he pronounced the tumor "nothing." Bull has tersely referred to his very common soothing expression of opinion by the remark that "a lump in the breast is never a 'nothing.'" In the same paper (Medical Record, August 25, 1894) he has also called attention to the frequent malignant degeneration of innocent growths. The physician who sees a breast tumor early should, in these days of advanced and advancing medical education, consider himself responsible for results if he cause delay of more than four weeks in active methods of attack.

If we condemn delay in cancers which can be seen or easily felt, what shall we say of those where the trouble is situated internally, as, for example, in the stomach? The more progressive members of our profession, recognizing that the disease is one to be removed by operation where a sufficiently early diagnosis can be made, have bent all their energies toward accomplishing this early recognition, and very satisfactory progress is being made. The examination of the stomach contents by chemical and other means, the gastroduodenoan, and other modern instruments and methods should enable us to make up our minds as to the necessity for exploratory incision before a tumor is palpable. If one waits until a tumor shall develop which is large enough to be felt, or until a stout patient shall have emaciated sufficiently to enable one to make satisfactory palpation, the case is already hopeless. If we are to have success in this field of surgery we must learn that early exploratory operation in suspicious cases is demanded. If on section nothing is found, then in these aseptic days the patient has risked little except a weakening of part of his abdominal wall, and if a cancer is found the conditions for its removal are better than they ever will be again. I have never seen a patient die of an exploratory section where no fatal disease was present, and I believe such cases must be exceedingly rare.

As an example of the waiting system, I may here refer to

CASE III.—This was a case of carcinoma of the transverse colon in a man of about forty-two years, where for a whole year the patient was under medical observation (N. Y. Med. Jour., September 1, 1894). He was operated upon by me, and the tumor, with about six inches of gut, removed. The man made a perfect recovery from the operation, and is still free from symptoms due to obstruction, but there will in all probability be a recurrence by metastasis, for there were many infected lymph nodes in the mesentery which could not be removed. The growth was a very slow one, and was due to degeneration of an adenoma. A radical cure might have been hoped for had the operation taken place six months earlier.

Intestinal Obstruction.—The next class of cases for attention consists of those where there is obstruction of any part of the intestinal tract. These are urgently surgical, as Dr. J. B. Murphy has said, "as soon as the diagnosis is made." Yet I have seen operation postponed day after day because some symptom indicating the gravest danger was absent; such a sign, for example, as fecal vomiting. The fact is that when there is persistent vomiting of any kind, with abdominal pain and obstipation resisting strong enemas, there must be present some anatomical, inflammatory, or neoplastic change demanding abdominal section. For the progress of the science of medicine I believe it may even be regarded as a misfortune when a patient gets well without operation where there has been foolish delay; for there are always illogical persons who will say that because A. B. got over an attack without the use of the knife therefore X. Y. ought to delay and not submit to operation. But it happens that A. B. suffered from fecal impaction, while X. Y. has an intussusception which threatens gangrene. However, even X. Y. may recover without section by a medical miracle and without thanks to his physician.

I shall never forget one of the first patients on whom I operated for intestinal obstruction.

She was a young girl of nineteen years who was admitted to the hospital, having had no stool for five days. The attack began with a sudden sharp pain immediately after drinking a glass of cold water. There had been almost constant vomiting ever since. When I saw her the temperature was under 100° F., and the abdomen was soft. The girl was conscious and had no severe pain, but vomited incessantly. Had it not been for a wretched, feeble, and rapid pulse her general condition might have been called good. Enema by long tube was almost without result. There was no bloody discharge. It was nine o'clock in the evening. One of my friends, a well-educated practitioner, saw the case with me and advised against operation because of insufficient diagnosis. I disagreed with him, and, though I keenly felt the responsibility, I operated that night, being led to my decision by the patient's miserable pulse and by the vomiting, which, by the way, was not fecal. Median abdominal section disclosed at once an immense intussusception involving more than two feet of gut. It was gangrenous, and I realized that the case was hopeless. Rapidly sapping off the free abdominal cavity, I incised the whole mass to relieve tension, but the girl died the next day. Cases like this have taught me that the gravest forms of intestinal obstruction may exist with little or no fever and without the classical sign of stercoraceous vomiting.

It was my intention to speak here of appendicitis, but the profession has been so long and persistently stirred up on the subject that it hardly seems possible that any one who reads the journals or attends medical meetings should err by delay in this disease. It may not be amiss to repeat, however, that appendicitis may exist without pain or tenderness in the right iliac region. Quite recently I saw two cases where fatal delay occurred because of the absence of this well-known symptom.

Euphema of the Mastoid.—This is far from a rare condition, and it is one of those where the percentage of neglect is perhaps higher than in any other disease. The pus is pent up in a region where spontaneous discharge, with the recovery of the patient, is almost an impossibility. It is, moreover, a region easily and very safely accessible to a skilled operator. Without evacuation, meningitis, thrombosis of the lateral sinuses, pyæmia, or some combination of
these deadly complications will surely occur. Yet, even in gravely suspicious cases, certain of the very men who make this part of the body the subject for special work and study will advise us to wait for meningeal irritation, which is simply the first step into truly dangerous territory.

I have yet to learn a satisfactory reason for delay where there has recently been middle-ear suppuration and where marked mastoid tenderness exists. If there is also fever, in spite of an open ear drum, the way is clear without waiting for any sign of extension of the disease. The stake is a heavy one, being nothing less than a human life; the risk of operation is a comparatively slight one. The opening of a mastoid filled with pus is certainly not entirely devoid of danger, but is absolutely necessary; while, if no pus is present, the procedure is not a particularly perilous one, and it may be productive of good, as, for example, where the bone is sclerosed or eburnated.

I do not wish to go over the whole field of surgery in this strain. I have merely spoken of certain types of disease which are of daily occurrence, and I have tried to show that neglect, unintentional though it be, is a frightfully common fault. The reasons for its existence are various. Probably one of the most frequent is an exaggerated idea of the dangers of the operation itself. It is not that I would belittle the seriousness of major surgical work, but that I wish to emphasize the point that no operation is ever knowingly undertaken by a conscientious surgeon where he believes his remedy to be more dangerous than the malady which is to be attacked. It is a rare thing in these days for an operation to be performed where the surgeon might later wish he had stayed his hand. The opposite state of affairs is, however, unfortunately too frequent. The vast majority of patients afflicted with malignant chronic disease come to the knife in time for palliation at best. Too many cases of appendicitis are first seen by the surgeon when peritonitis or general sepsis already exists. Only too often is a suppuration of the mastoid cells permitted to go on to fatal meningitis under the very eye of the physician.

A few weeks ago I saw a woman who had been for several months treated with caustics and lotions for the cure of a fungating ulcer which began in a little mole on the heel. Her medical adviser disregarded the fact that after each application the granulations sprang up with increased vigor. The patient finally secured the services of a good diagnostician, who, at once recognized malignancy and proposed the removal of the growth. When he was about to operate, several skin nodules were found in the leg, and the woman was sent to the Mount Sinai Hospital for amputation of the thigh. It was here that I first saw her. Examination of one of the nodules showed the tumor to be a melanotic myxosarcoma. The patient now refused to submit to operation and went home. At last accounts a regular (?) practitioner of this city had guaranteed a cure without the use of the knife.

Another reason for wrong delay may be ascribed to unscientific medical education and a consequent dependence on stereotyped combinations of symptoms learned from books, as a picture of disease. Such knowledge is parrot-like, and he who depends upon it must be misled and con-

fused by any departure from the fixed nosological type. He is tempted to wait for what he considers a clearer expression of the disease as he has learned it, and the precious time is gone.

Accurate diagnosis is a scientific and most satisfactory thing. Treatment without diagnosis is foolish and often worse; but there is in surgical disease a golden middle way too seldom traversed where the Gordian knot may be loosed by means of the scalpel. I refer to the making of an intelligent partial diagnosis—that of "case for operation." I do not believe in carelessly opening the living human body as a child breaks his toy, just to see "what's inside," but if there are logical grounds to suspect that there is something inside which ought to come out, delay can rarely be productive of good.

35 EAST THIRTY-FIRST STREET.

CREOSOTE

AS A SPECIFIC IN TUBERCULOSIS

WHEN USED IN LARGE DOSES.

BY JOHN R. CONWAY, M. D.,

ASSISTANT VISITING SURGEON TO BELLEVUE HOSPITAL.

Nearly three years ago, having become convinced that the use of creosote in large doses was the best treatment in pulmonary tuberculous disease, and the only method that could be safely used with any certain beneficial effect, I had the opportunity to use it in a sufficient number of cases to demonstrate that it certainly had the power to absolutely check the progress of the malady, and in many cases, when used early enough and continued for the proper length of time, to be even curative. I have not confined my observations to the action of this drug on pulmonary tuberculosis alone, but have used it extensively in almost all forms of the disease, including the peritoneal, joint, bone, glandular, and laryngeal varieties. Out of nearly four hundred cases treated in private practice and in Bellevue Hospital I shall give the histories of a few typical ones illustrating the almost specific action to be expected. So far I have not been disappointed in a single instance, and the results have been more than satisfactory. It seems certain that with the more general use of creosote in the manner that the cases quoted here have taken it, the conclusions of Sommerbrodt will be confirmed by every one persevering enough to follow his directions. I have had no difficulty in getting the stomach to dispose of twenty-minim doses without any unpleasant symptoms to the patients, many of whom before commencing the treatment suffered from intense gastric irritation with vomiting and indigestion. Great stress must be laid upon the method of administration and the quality of creosote used. My invariable practice now is to prescribe it in capsules mixed with cod-liver oil in the proportion of one to two. Two sizes of capsules are used, the smaller one containing two minims of creosote and the larger four minims. The latter makes a medium size which most persons can readily swallow, and has the advantage of being of almost the same price as the smaller one.
The dose should always be given immediately after eating and never on an empty stomach.

Many have failed to get good results from the use of the large doses of creosote because of the drug being contaminated with impurities; others, from want of patience, expecting too much in a short period, and not making allowance for the expected disagreeable eructations during the first few weeks. Because of these unpleasant symptoms at first produced, but which would surely disappear after persistent use, the treatment has been stopped and condemned as worthless.

To avoid the difficulty arising from using an inferior quality I have the capsules manufactured by a reliable firm, who take the greatest care to get an absolutely pure drug; consequently all my patients exhibit the same results, and none of them have ever had to stop the use of it because of any ill effects upon the digestion.

At the present time the first patient whose case is given in this article has taken more than thirty thousand minim of creosote (in this form) within three years, and he has perfect digestion and a good appetite, and shows no signs of kidney irritation.

Another point to be remembered is that many persons with pulmonary tuberculosis when first seen by the physician are already affected with intense gastric irritation. It is therefore necessary to alleviate this and quiet the stomach before beginning the use of creosote. For this purpose I use bromide of sodium, fifteen grains, subnitrate of bismuth, ten grains, and pepsin crystals, three grains, to be taken every four hours. After twenty-four hours of this treatment the administration of creosote should be begun, first using two-minim doses after each meal, and increasing the amount gradually when the stomach becomes more settled.

It will always be found that after several days complete tolerance will be established, and within four or five days the dose can be gradually increased, until finally the stomach improves in every way, and all irritation with the accompanying indigestion has been relieved.

In regard to the method of increasing the dose, the following rule will be found to work well: begin with two-minim doses three times a day; in acute cases increase the dose by two minim every fourth day until twelve minims are given at one time, then observe the results of the largest dose for several weeks, and, if the improvement is not satisfactory, carefully add two minims more every eight or nine days until a twenty-minim dose has been reached; then persist with this quantity until the symptoms warrant a diminution of the amount. I have frequently used the highest dose for four and five months at a time before decreasing it, with the most satisfactory results. The chronic cases do not, as a rule, require so large a dose, or to have it so rapidly increased. In my average chronic cases the patients use twelve minims three times a day, commencing with the small quantity (two minims), increasing by two minims every six days to eight minims, then every second week to twelve minims, according to the effect.

In every case in the first week or ten days there are troublesome eructations of gas flavored with creosote; but I have not yet seen a single instance where this did not entirely subside after the creosote had corrected the fermentation caused by old indigestion, which it invariably does. This feature of its action has struck me so forcibly that I am now using two-minim or four-minim doses in many cases of dyspepsia and bowel indigestion, with more rapid curative results than I was ever able to get from any other method of treatment. The great increase in the weight of all tubercular patients under this method of treatment is very largely due to the great appetite and perfect digestion they quickly obtain, because of this curative action of the creosote on the functional disorders of the stomach and bowels.

In some cases where the anemia is profound I also use iron and arsenic, the latter in very small doses—one two-hundredth grain three times a day.

After a short time there is no necessity for the use of cough medicines or, in fact, any other drugs.

At first it was my custom to use creosote inhalations, but I have since dropped this altogether, as it became evident it was unnecessary and sometimes did far more harm than good, causing irritation and laryngeal inflammation.

The treatment now is so simple and the cost so slight that it is within the reach of all, and even the most ignorant can be made to follow it up successfully. One trouble I sometimes experience is that many patients do so well that they do not believe they have consumption, and cease the treatment after five or six months, only to be warned of their folly when the active symptoms recur, and rapid loss of strength and weight brings them back to it more obedient than before. It is well to impress all patients with the absolute necessity for keeping under the influence of the treatment for at least two years, no matter how well they may seem. I am of the opinion that many will require four years’ constant dosage before they can safely cease the use of it, while others, who began treatment earlier, before extensive deposits were formed, can be said to be free from danger after two years. It must also be remembered that the expected specific effects take place very much more rapidly in cases diagnosticated soon after the origin of the disease; this is particularly remarkable in acute pulmonary tuberculosis. I have seen the temperature reduced to normal within three weeks, without any rise occurring afterward, in a patient who had been suffering with this peculiar form for less than a month. She was able to leave her bed in two weeks, and was discharged from the hospital at her own request within a month.

After a year of the larger doses the average patient can be kept safe from relapses on about eight minims after each meal, provided no active symptoms are present at the time, as would be indicated by even one degree of rise of temperature.

The first history will illustrate the worst form of acute pulmonary tuberculosis, which had progressed for nearly four months before the large doses were first used. It was apparently a hopeless case, and yet has been one of the most successful.

Case I. Acute Pulmonary Tuberculosis.—B.M., aged twenty-one years; no tubercular family history. Before he was taken
ill he weighed one hundred and thirty-five pounds, and had always been in good health. The letter part of January, 1892, he first began to complain of cough accompanied by pain in the upper portion of the right side of his chest, and gradually a fever developed, which would be pronounced each night and less during the early part of the day. He was first examined by me in March following, and I then found the whole of the upper lobe of the right lung consolidated. His spuva contained tubercule bacilli in large numbers, and was at times very thick and tinged with blood. His temperature was 104°; pulse, 120; respiration, 36.

There were present great general prostration, complete anorexia, severe dyspnoea on exertion, and night sweats. He was ordered to bed, put on easily digested food, and daily doses of antipyretics were used, combined with sedatives. The disease spread rapidly, and within two weeks had invaded the lung lower down, almost to the upper border of the lower lobe.

He was losing weight rapidly, and did not go over one hundred and fifteen pounds. The morning temperature averaged 102°, the evening 104° to 105°.

By April 1st the spuva had lost the rusty look and had become purulent, but very profuse. The temperature and other symptoms remained unimproved, the emaciation going on rapidly, and the prostration was so great he could not arise from bed without help. About this time (April 1, 1892) I began to use creosote in two-minim doses and by inhalation, without any noticeble effect. In the middle of April Dr. A. L. Loomis saw him in consultation, and, after a careful examination, confirmed my diagnosis of acute pulmonary tuberculosis, probably becoming general, as he then began to have profuse diarrhoea, with abdominal pains, and the lower extremities became edematous. He expressed his opinion that the case was a hopeless one and would prove fatal in a short time. There was no improvement in any of his symptoms, the pulse having become weaker and as high as 140, with a temperature of 104° to 105°.

The lung had evidently commenced to break down in places, as evidenced by the physical signs. May 1, 1892, I determined to try the effect of rapidly increasing the dose of creosote by two minims at a time. This I did every fourth day until he was taking twenty minims three times a day.

The result was that within two weeks his symptoms showed a very marked change for the better, the temperature never rising higher than 102°—after the dose had reached twelve minims. May 9th he weighed only ninety pounds. July 15th, when he was able to be out of bed, his weight was a hundred and fifteen pounds, an increase of twenty-five pounds in two months. With the decrease in the temperature the appetite and digestion returned and the patient's general appearance by June 1st was so improved as to be marvelous to his relatives.

The cough continued severe and the expectoration profuse, July 15th: Temperature at the highest was 101° at night and frequently only 99° in the morning. He was strong enough then to be dressed and move about his room, but of course was very weak and easily fatigued.

The physical signs in the lung showed that as soon as the fever decreased the active involvement of the lung ceased, and the consolidated area slowly resolved in part, but there were still numerous bacilli present in the spuva.

August 15, 1892.—Morning temperature, 99°; evening, 100°; weight, a hundred and fifteen pounds; cough and expectoration less, but still very troublesome; no night sweats, and strength gradually increasing. The anemia, which had been profound, was getting less marked under the administration of tincture of the chloride of iron. During this month, as the temperature did not fall to normal, I increased the dose of creosote to twenty-two minims three times a day.

September 15th.—Improvement continues, the temperature being often normal in the morning and 99.5° at night. The large doses kept up.

October 15th.—Temperature frequently normal all day, but at times there is a slight rise in the evening. The consolidated area decedely less, but still distinctly marked.

November 15th.—Weight, a hundred and twenty-seven pounds; temperature normal at all times; tongue clean; appetite good. Patient able to be out of doors and takes regular daily walks. Expectoration growing less during the day and only troublesome after first getting up in the morning. Dose of creosote diminished to eighteen minims three times a day.

January 15, 1893.—Weight, a hundred and thirty-one pounds. General condition greatly improved; he has been able to be out of doors every day during the winter. The dose of creosote is still the same. The cough is infrequent and the chest is entirely free from rales, but a consolidated area about two inches in diameter can be found at about the angle of the scapula posteriorly. The temperature has remained normal at all times. The urine has been carefully examined and found normal.

January 15, 1894.—One year has elapsed since the last note, and during this time the creosote has been gradually diminished to eight minims three times a day, which now seems to hold the disease in check; the temperature remains normal and the consolidated area has diminished about one half, but can still be marked out. There is no cough or expectoration, and he feels in good health. The weight is now a hundred and thirty pounds.

For the past six months repeated examination has failed to find the presence of tubercule bacilli in the expectoration.

May 1, 1895.—The patient has been constantly using eight minims three times a day. The consolidation has almost entirely disappeared, but, although advised to cease treatment for a time, he is too timid, and still persists. He weighs a hundred and thirty-two pounds and is in as good general health as he had ever been before being taken ill with this disease. He has no cough and no expectoration. Temperature normal.

Case II. Chronic Pulmonary Tuberculosis.—F. B., aged twenty-three years, first noticed that he had a cough and began to lose weight in December, 1891. His symptoms did not trouble him very much excepting the gradual emaciation, the cough which could not be checked, and loss of strength, which was progressive until October, 1892, when he had a severe haemorrhage from the lung. This was repeated four times to January 30, 1893, when he first came under my treatment. Previously to his illness his weight was a hundred and forty-five pounds. When examined by me he weighed a hundred and twenty-five pounds; he had just had a large haemorrhage, and his temperature the following day was 103°. Night sweats had been present for about three months. The expectoration had been increasing and the cough more troublesome. Physical examination showed both spiccs consolidated, the right side more so than the left, but no cavities could be made out. The use of creosote was begun at once and run up to sixteen minims for a dose in four weeks, at which time the temperature became normal and remained so. In six weeks he weighed a hundred and thirty-five pounds; had had no more haemorrhages, the night sweats were checked, his cough and expectoration lessened, and his general appearance became one of health. He was allowed to remain on the sixteen-minim doses for six months longer, and then the quantity was gradually decreased by four minims every two months until the last six months of treatment, when only four-minim doses were used. For the past six months he has ceased the treatment and remains in perfect health (March, 1895).

He now weighs a hundred and fifty pounds, much more
than when in ordinary health before the onset of the tubercular.

**Case III. Chronic Pulmonary and Laryngeal Tuberculosis.**

A. M., aged sixty years, was first seen by me in January, 1893. He gave a history of having had a chronic cough with expectoration for the past three years. At times he would have night sweats and would be flushed and feverish in the evenings. Within two years he had gradually lost weight to the extent of twenty pounds. Early in 1891 his voice became husky and the cough frequent and irritating; this increased month by month until 1892, when he was unable to talk above a whisper, the voice being completely lost. He had been going to various throat specialists, none of whom gave him any hope of regaining his voice. On examination I found both apices of the lungs consolidated to a slight extent and evidences of chronic bronchitis. The evening temperature averaged 100°. Weight, a hundred and twenty-five pounds. Anemia pronounced, anorexia and indigestion present. Laryngoscopic examination revealed a considerable infiltration on either side of both vocal cords, the left side more markedly swollen and the left cord pushed toward the center and incapable of motion; no ulceration present, but the whole larynx chronically congested.

Dr. C. C. Rice examined his throat later and gave me very little hope of being able to effect a cure, saying the infiltration was evidently tuberculous, but advised local and constitutional treatment.

I began at once using four minims of cresote after each meal, and within one month increased the dose gradually to twelve minims, at the same time spraying the larynx with five grains of nitrate of silver to the ounce of water every third day, allowing him to use frequently a sedative spray. Iron and arsenic in small doses were also ordered.

In three months his general condition had very greatly improved, the cough and expectoration were much less, fever was entirely absent at all times, appetite and digestion were normal, and the weight had increased to a hundred and forty pounds. The voice had begun to return, the infiltration in the larynx was very much less, and the left vocal cord moved to a slight extent when an effort was made to phonate.

**October, 1893.**—All the improvement has continued, the voice now being quite distinct but husky. Weight increased five pounds; infiltration in larynx continues to lessen. Cresote diminished to eight minims three times daily.

**January, 1894.**—Continues to do well, the voice growing more distinct each month and the general appearance of the larynx more normal. He is able to talk distinctly and loudly, but is somewhat hoarse. The cough has almost ceased, expectoration disappeared; weight, one hundred and fifty pounds; apices slightly consolidated, but markedly less than a year ago; treatment continued.

**Case IV. Tubercular Peritonitis simulating Appendicitis: Operation: Diagnosis and Recovery.**—W. McFarland, aged twenty-seven years, admitted to Ward 5, Bellevue, June 9, 1893. Sister died of pulmonary tuberculosis. Five months before admission he began to suffer from pain in the region of the caecum. Having been carefully examined by several of the visiting staff, it was concluded that the patient was suffering from an ulcerated appendix, which had not yet perforated, and that an operation for the removal of the appendix was urgently indicated because of the frequency of the inflammatory attacks. Accordingly, agreeing as to the diagnosis, I proceeded to operate (July 15, 1893). On opening the peritoneal cavity I was surprised to find the caecum, ascending colon, small intestine, and parietal layer of the peritoneum covered with small, round, whitish, elevated growths, evidently a tubercular inflammation, which was more marked in the region of the caecum, which was adherent to the surrounding structures, and the appendix vermiformis lay below and beneath the caecum, closely adherent to it, but showing no signs of disease. There was no fluid in the peritoneal cavity; so, after a careful examination, the opening in the abdomen was closed, no drainage being used.

The patient made a speedy recovery from the effects of the operation, and within a few days was placed upon the cresote treatment, the dose within a month being increased to ten minims three times a day.

He has steadily gained in strength and weight, and, although still suffering at times with sharp pains in the region of the caecum, his temperature remains normal, appetite good, and general appearance very much improved.

The abdomen is not swollen, but appears normal in every respect. There is no local tenderness, there are no night sweats, there is no fever, and notwithstanding hospital confinement there is every indication of recovery. As he left the hospital in June, 1894, I have since lost observation of him.

130 Lexington Avenue.

**SUCCESSFUL MECHANICAL TREATMENT OF SOME UNUSUAL AURAL CONDITIONS.**

By Wilbur B. Marple, M. D.,

Assistant Professor of Ophthalmology at the New York Polytechnic; Assistant Surgeon to the New York Eye and Ear Infirmary.

The writer has employed with success a mechanical device in the treatment of certain rare aural conditions to which he desires to call your attention this evening. The history of the first case briefly is as follows:

**Case I.—K. D., a married woman, aged about twenty-five or thirty years, first came under the writer's care October 3, 1893. She has been troubled very much for a year or more with vertigo. For this she had been treated for some weeks by her physician, a most intelligent and competent man of large experience. Everything about her general condition had been carefully examined, every disorder which could in any way cause her vertigo had been corrected, but still the annoying symptom persisted. Inasmuch as the patient always referred the vertigo in its beginning to her right ear, she was finally sent to the writer for examination and treatment. She says that the vertigo only comes on when the head is held in a certain position—viz., when it is tilted to the right, as when she is lying on her right side at night, or when the head is tipped back and to the right. The vertigo is so severe that she often suffers from nausea, and vomited on one occasion.

She has some tinnitus on the right side. Examination reveals the following: H. D. R., watch, one foot. H. D. L., watch, fifteen feet. Relation of bone and air conduction on both sides was normal. The bone conduction was somewhat greater on the right than on the left.

The lower tone limit on both sides was not changed. A fork of thirty vibrations to the second was heard distinctly. The upper tone limit, as indicated by Galton's whistle, was also normal.

During inflation by Valsalva's method it is impossible to discover any movement of the membrana tympani. The patient does not notice any difference either in the quality or intensity of high musical tones, in changing her head from the vertical position over toward the right side, in which position she always suffers from vertigo.

* Read before the Hospital Graduates' Club, New York, March 28, 1895.
The right membrana tympani is somewhat retracted and thickened, and in its periphery there are some calcareous deposits. Inflation by Politzer's method influences the hearing very slightly.

The patient was treated by inflations for a few days, but with no relief.

The writer congratulates himself that it was his good fortune during the treatment of the case to have the benefit of numerous useful suggestions from that most skillful aurist, his friend Dr. Edward B. Deuch, to whom, moreover, he acknowledges with pleasure his indebtedness for bringing to his notice about this time an article by Dr. Clarence Blake, of Boston.*

In this article, entitled Mechanical Treatment of Tension Anomalies in the Ear, Blake describes, among others, the following case, which was of such interest that brief allusion will be made to it:

A violinist noticed that when he tilted his head over to the left side, as is the custom in playing this instrument, the tones of the violin sounded dull in the left ear, and at the same time his ability to recognize the differences in quality of notes (timbre perception) was much impaired. The hearing was good, and examination revealed only an intact membrana tympani and a small, round, dry perforation of Shrapnell's membrane. Valsalvan inflation disclosed a considerable movement of the membrana tympani outward, and evidenced a relaxation of the tensor tympani, malleo-incudal capsular ligament, and the corresponding attachments. Blake regarded this ligamentous looseness as the cause of the symptoms, inasmuch as the latter only came on with the head in a certain position. To overcome this excessive ossicular mobility a most ingenious device was employed. He took a small piece of the rubber dam used by dentists (about twelve millimetres long and three millimetres broad); this he inserted in such a way into the auditory canal that the ends lay against the anterior and posterior wall of the meatus, while the central bent portion rested against the short process of the malleus. Thus a pressure from without was exercised (estimated by Blake to be equal to about fifteen milligrams) which was in a direction favoring the most complete opposition of the malleo-incudal articulating surfaces. This pressure from without counteracted in a measure the effect of the traction from within. With this rubber in position, the symptoms in Blake's patient (impaired timbre perception) disappeared. It was found necessary to change the shape of the rubber several times before getting the maximum effect. When just the right shape had been secured the patient wore it several weeks with ultimately permanent relief to all his symptoms. Blake's case, and that treated by the writer possessed this feature in common, that certain symptoms came on with the head in a certain position. This symptom was, in Blake's case, loss of timbre perception; in the writer's, vertigo. It was determined to make use of this device, and on October 14, 1893, a small piece of rubber was introduced after the manner employed by Blake, as described above.

October 18, 1893.—Rubber still in position. If anything, the patient is better. She can now sleep on her right side, which she could not do before.

25th.—Says she still has the vertigo, but that it is much less severe. Changed the shape of the rubber slightly. Two weeks later, as a sort of control experiment, the rubber was removed. Two days later she returned, saying that the vertigo had been very much worse than it was when the rubber was in place. The day following its removal she had it very bad, with much nausea. She is anxious to have it reintroduced. Used Siegel's otoscope to discover whether there was any twisting movement of the handle of the malleus. When the air in the meatus was rarefied or condensed no such twisting could be detected.

November 6, 1893.—One week later she reports that she has not had a trace of vertigo since the rubber spring was replaced. The hearing distance of the right ear has gone up from one foot to twelve feet, simply as the result of some change produced by the pressure caused by the spring.

21st.—Five days later: No recurrence of the vertigo. II. D. R., fifteen feet.

December 21st.—No return of the vertigo during the past six weeks until the day before yesterday, December 19, 1895, when on rising she found that it had returned, and ever since it has been most distressing. II. D. R. watch has fallen to three feet. Examination revealed that the rubber was no longer in contact with the malleus, and when it was removed it was found to be dry and stiff and possessed no elasticity, having been in position for five or six weeks. A new piece was introduced. A week later it was readjusted, as it was not in good position. Worn for a week. The vertigo was better, but not entirely absent.

Can sleep on her right side. The shape of the piece was modified several times, as it was discovered that unless it fitted nicely and pressed exactly on the short process of the malleus the effect was nil. She noticed about January 15th that the motions of the head which produced the vertigo are not so limited in character—i. e., the only motion which does not produce the vertigo is a motion to the left. Her condition during January varied, though she was not entirely free from the vertigo.

March 13th.—Has been much annoyed of late. Can not get up, can not sit down, can not move in any direction without vertigo. Inserted a small paper disc against the membrana tympani in the posterior quadrant. When she returned in a few days the disc had fallen out, and, of course, her condition was unchanged. Put in another disc. A week later she returns much improved. She can move around and turn without vertigo. The disc was pushed tightly in against the membrane.

Ten days subsequently she returned, and reported that since leaving the last time she had not had a trace of vertigo, being absolutely relieved. She could move in any position, could get up suddenly, and her whole head felt better. Two days ago, after coughing rather vigorously in the evening, she seemed to feel the disc move. Since then she has not felt so well. She has had no vertigo, but her head has felt somewhat uncomfortable, and she has had one or two momentary feelings like being seasick. She has not felt badly enough to come to the city for that alone, but as she was in the city she thought best to consult the writer at his office. Examination showed that the disc was not in contact with the membrana tympani except at its periphery. It was therefore pushed back again in good contact with a cotton-tipped applicator. The patient was not seen again for a month, during which she has been entirely free from vertigo until last night, when it returned. She was very much disturbed on reaching my office. Examination again revealed that the disc was not in contact with the membrana. It was again pushed back firmly against the membrana. The patient was seen five hours later the same afternoon, and reported that her vertigo and nausea had entirely disappeared from the time the disc had been replaced. Six weeks later, June 22d, has not had a trace of vertigo or nausea since the last visit.

One month later, July 21st: Went to bed all right last night. On rising, about seven o'clock this morning, she had much vertigo and nausea. Examination revealed the disc dislodged and quite a distance from the membrana. It had not been touched for ten weeks. It was pushed back. Ten days later, July 30th, she reports that the vertigo gradually disap-

* Archives of Otolaryngology, xxi, No. 2, p. 166.
peared after her last visit, though not as promptly as it had done before.

November 5th.—Four months later: Has not had any vertigo since the last visit. The ear feels normal in all respects. In December took out the paper disc. Early in February she wrote me that the ear seems to be entirely well. She still has tinnitus, but no vertigo. She trusts the cure will be permanent.

(A similar favorable report was received this week, March 20, 1895.)

Case II.—II, H., aged twenty-four years, Wilmington, Del., seen March 29, 1894. Has noticed for three or four years that his hearing in the right ear was somewhat impaired, and also that when certain musical notes are sounded in his vicinity there is a buzzing or rattling in his ear, lasting while the note continues to sound. This is especially noticeable when his brother, who has a baritone voice, sings in his vicinity. The note E seemed to be the one which produced the symptom to the most marked degree.

H. D. R., watch, eighteen inches; H. D. L., watch, seven feet. Membrana tympani almost normal, but there are some calcareous deposits in its periphery.

The upper and lower tone limits are normal. Inflation produces little change in the hearing. Inserted rubber spring. He said that at a dinner where a gentleman made a speech in a monotonous voice there was a certain note in his voice which, when struck, would almost set him crazy, producing in his ear a sound like the buzzing of a paper over a comb. When he poured water out into a bowl it would sound as though there was water in his ear (as after sea bathing). He could also start it by leaning forward and whistling. Also he seemed able to "tire his ear into it," for in playing accompaniments for a person singing on his right side he would not be annoyed during the first three or four songs. Then it would begin, and any note or song would set his ear buzzing.

April 8, 1894.—Has tried, repeatedly, since the rubber was inserted, having his brother sing in order to get the rattling in his ear. Only once, just a little bit, has he succeeded; at all other times it has failed.

Seven months later, November 22, 1894: He has not been annoyed at all of late, except once, at a performance of Rob Roy, two weeks ago. When the cornet in the orchestra struck a loud note it made his ear buzz a moment; but this was only momentary, and no other note or singing produced it. Inserted a paper disc.

Case III.—Helen G., aged nineteen years, seen April 13, 1894. Complains of exactly the same symptom,—of a disagreeable buzzing feeling in her left ear when certain musical notes are struck in her vicinity. Functional examination revealed the ears normal. Inserted rubber spring. Seen one month later. Since the rubber has been in position she has not once perceived the buzzing in her left ear.

In regard to these last two cases their explanation has been given by Helmholtz in The Mechanism of the Ossicles of the Ear. This buzzing sound is often produced in the ear as the result of very loud tones. As is well known, the articulation of the malleus and incus is of such a peculiar coglike character that when the malleus is driven inward the incus is pushed along too by the coglike arrangement of the articulation; but when the malleus is driven outward the cogs separate, leaving the incus behind. Helmholtz considers the jarring sound in the ear when loud tones are struck to be caused by the cogs. "When the excursions of the membrana tympani are very great, and during the outward phase of the vibration, the anvil is not driven outward with any considerable force, and can not therefore follow perfectly the excursions of the hammer. The result of this is that the ossicles are separated, and that during the next vibration inward the anvil receives a blow from the returning hammer. This mechanism is also well adapted to the production of combinaison tones, and the peculiar sensation of buzzing in the ear resulting from the combinaison tones of two strong soprano voices when thirds are sung can be referred to this jarring which takes place between the hammer and anvil." When these buzzing sounds are present to an abnormal degree one could well imagine an undue looseness of the ossicular ligaments. If the cogs are widely separated, as by increasing the air pressure in the middle ear, the buzzing ceases. Also in case the ligaments are too loose the introduction of the little spring in the manner described would tighten up the articulating surfaces and put them in such close contact that the buzzing would cease, as was true in the last two cases.

Now let us consider briefly some features of the first case. Let us look at all the conditions without prejudice for or against, and see whether we are really justified in holding that the mechanical devices used had anything to do with the disappearance of the vertigo.

That the latter was of aural origin was always suspected by the patient herself, who referred its inception invariably to the right ear. Always during the persistence of the vertigo her right ear felt "stuffy," and the tinnitus was worse. Again, the hearing in that ear for the watch was at first only one foot, while in the left it was fifteen feet. Inflation did not improve the hearing in her right ear. But after the rubber spring had been introduced so as to fit, examination showed that the hearing distance for the watch had increased on that side to twelve feet.

That the symptom was some tension anomaly, probably due to some ligamentous laxness, was suggested by the fact that the vertigo was always brought on by tipping the head to the right side, or back and to the right. In the commencement of the treatment the writer was extremely skeptical as to the influence of the devices used in relieving the symptom. There had previously been times during which she had been free from her trouble, so that one naturally would at first consider that the disappearance of the vertigo after employing the device was simply a coincidence—merely a case of "post" but not of "propter." Yet this "coincidence" became such a very frequent occurrence that one was no longer justified in regarding it as merely a "coincidence." Let us recall a few only of these. The patient comes in; the rubber has been in position about three weeks, and her vertigo has been much less. As a "control" experiment rubber was removed. Two days later she returned, saying that the vertigo had been very much worse the past two days. She has had nausea, and is anxious to have the rubber reintroduced, which was done, and at her next visit, a week later, she reported that she had not had a trace of vertigo since the prop was replaced.

Again, after the use of the paper disc was begun she had gone for two weeks with perfect comfort; could put the head in any position without bringing on her old trou-
ble. After coughing violently she felt the paper disc in her ear move, and at once her vertigo returned, and with this there was an uncomfortable, stuffy feeling in the ear. On examination, the disc was found tilted away from the drum membrane, having been dislodged very probably at the time she coughed. With a cotton-tipped applicator the disc was pressed firmly back in position. She was requested to return the same afternoon, which she did. Her vertigo had entirely disappeared, and she was not seen again for a month.

Such experiences as these became so frequent that the writer's skepticism vanished, and he was convinced that the pressure exerted by the rubber, and eventually by the paper disc, was the aetiological factor at work in relieving his patient.

As to how it did this one can only speculate, in the absence of more exact knowledge in regard to the phenomena of vertigo. Dizziness as the result of rotation has been studied by several observers in normal men and in deaf-mutes, but a comparison of symptoms, with pathological changes in the internal ear, has been made in extremely few cases. Dr. Frederick S. Lee, of this city, who has himself made elaborate investigation as to the function of the semicircular canals in fishes, kindly gave the writer the benefit of his experience. It was his opinion that, reasoning from his observations in fishes, one could locate with probability the lesion, if it was in the semicircular canals, by the direction in which the patient seemed to be falling during the attack of vertigo. The fact that in the writer's case "the motion was circular, everything seemed to go around," would seem to indicate that no one semicircular canal alone was disturbed, but all, or possibly, as Dr. Lee suggests, "the oto-lithic parts." Also, this disturbance in the labyrinthine pressure might be produced by a minute movement of the osicular chain attending a tilting of the head if the articular ligaments were loose. In considering certain aural conditions, one is oftentimes impressed by the conspicuous character of the symptoms which are produced by exceedingly minute changes in the parts. For example, Helmholtz has shown that the excursions of the stapes in the fainter (though yet clearly to be distinguished) tones must be so small as to escape detection even with the highest powers of our modern microscopes. A similarly minute movement could well be sufficient to bring about pressure changes in the labyrinth capable of causing the vertigo.

In conclusion, there are one or two points in regard to the technique to which it may not be amiss to allude. The little piece of rubber is seized by its two ends with the angular ear forceps; the convex-bent middle is smeared with a little vaseline; it is then inserted through the speculum until it is in contact with the short process of the malleus. The rubber is then released, one end falling against the anterior, the other end against the posterior, wall of the meatus. It is now carefully examined to see whether it is in accurate contact with the short process. To be sure of this, it is well to push it back lightly with a cotton-tipped applicator. The soft rubber produces no irritation, and the patient is not conscious of the presence of anything unusual in the ear. It is sometimes extremely difficult to remove the rubber, as it clings either to the membrana tympani or to the wall of the meatus. To facilitate the removal, the writer passed a fine silk thread through the layers of the rubber about its middle, but tied no knot in the silk. The end of the silk thread was cut long enough, so that when the rubber was in position the thread lay in the meatus, and could easily be seized with the forceps and thus the rubber pulled out. Once only was any irritation produced, and that was when he tied a knot in the silk, and this knot, when the rubber was in position, pressed upon the membrana tympani, producing pain and redness, so that the device had to be removed. He then passed the silk through the layers of the rubber and tied no knot in it, and no further irritation was produced.

The paper disc can be inserted by smearing the end of a cotton-tipped applicator with a little vaseline, pressing it on the disc, which thus adheres to the applicator and can be pushed into position. When it is in contact with the membrana tympani it remains adherent there on withdrawing the applicator. When it is desired to remove the disc it can be syringed out with warm water, or a short piece of fine silk thread can be attached to the middle of the disc by a bit of wax. This thread can then be seized by the forceps when the disc is in position, and thus the latter can be readily removed.

As Blake says: "The treatment must be long continued to get any permanent result in a condition which has become essentially chronic by the time it is brought to the attention of the surgeon.

"Still further, it should be said that the adjustment of such mechanical appliances must always be a matter of more or less experiment, since the questions of the weight and position of, and the degree of pressure exercised by, the dressing are variable factors, which must be apportioned to the individual needs of the case under consideration.

"The fact, therefore, that the application does not give immediate relief by no means justifies the conclusion that it can not be of service, since the effect may follow later, or may be more immediately brought about by slight change in adjustment."

No. 20 West Thirty-first Street.

REPORT OF A CASE OF WRITER'S CRAMP TREATED BY STATIC ELECTRICITY.

By S. H. Monell, M. D.,
Brooklyn.

March 29, 1895.—Miss —, telegrapher, aged twenty-five years. She has been telegraphing for five years. Her right hand has been falling for two years and is now practically useless; the left hand is also nearly useless. She can only clumsily push the key. She keeps at work, but must soon give up if she is not relieved. She has tried various mechanical devices, and has had some medical treatment without benefit. Her wrist is powerless, there is some distress and pain in the arm, and the thumb twists off the key. The patient is anemic and neurasthenic, but has never lost a day on account of sickness, and she considers her general health fair.

Upon careful inquiry, and finding that her right arm had
failed so early in her work when it had been easy to do, I concluded that the lapse of time (two years) and the nature of her case rendered the prospect of relief discouraging. I therefore frankly informed her that I could feel no hope of doing her much good, but that I would treat her for a short time, and, if she derived any benefit, well and good, and if not, then I would cease treatment. She was somewhat disheartened but acquiesced.

A five-minute application of static electricity was made to her right arm simply as a test of the muscular condition, but, after making her use the key (a telegrapher's instrument which I keep for the purpose), I observed an evident increase in the facility of her fingering.

March 30th.—She reports that her arm felt more comfortable all night and was nearly free from the usual sense of distress. Duration of treatment to-day, thirteen minutes. The arm felt better after the application. I advised very mild exercise for both arms and placed her upon appropriate treatment for her anemia.

April 1st.—The patient having rested for a day, her arm felt benefited, and she said that the operator at the desk next to hers had told her on Saturday that she "sent better." Duration of treatment to-day, fifteen minutes.

April 2d.—The patient reports that she "sent" fairly yesterday after her day's rest and treatment, but about 5 p.m., her arm got very heavy and felt poorly. Her working hours are from 10 A.M. to 6.30 P.M. The day was rainy, and on such days her arm usually felt worse.

April 3d.—She reports a steady improvement. She was able to use her arm all the morning. Her wrist is regaining power. Other operators tell her they notice that she "sends" a great deal better than formerly.

Increased strength of application to-day, but was careful to avoid all fatigue in treatment.

April 4th.—The patient reports that she "got all through her work yesterday without a bit of trouble by using her fingers easily and slowly." It is fully two years since her arm acted so well. The general muscular condition of her arm has improved and the pains have almost ceased.

April 5th.—The gain continues; a steady, small advancement each day. The arm did better yesterday than it has done any day so far. In view of her two years' experience with other treatment, she states that the gain to her seems "wonderful."

April 6th.—The arm felt better yesterday, although she had a hard day's work. About 5.30 P.M. the upper arm (biceps) began to feel lame. In the evening, however, it became rested and felt natural, there being no more of the former distress and nerving sensations. She stated that she had not been so greatly benefited by the treatment she could not have done such a day's work, but would have had to go to the superintendent and ask to be transferred to other duties.

April 7th.—She had another busy day on Saturday and the arm did well, but it got tired toward the close of the day. The patient timed herself on one message of seventy-two words which she sent in two minutes. As her work is mostly cipher work, requiring especial care in sending, she considered her speed excellent. To-day (Sunday) she is able to rest.

April 8th.—Repeated treatment as usual—about fifteen-minute applications. Her Sunday's rest was very grateful to her arm.

April 9th.—The patient had a very hard day's work yesterday, equal to a good day's work for any ordinary operator in perfect health. About 4 P.M. her arm got tired and she was obliged to take her thumb off the key and use her fingers only. No pains recurred, and no distress followed at the close of the day. She became annoyed at having so much work put upon her when she needed relief in order to benefit by the treatment, but to her protest the manager replied, "Oh! you seem to be doing well enough."

April 10th.—She had only a moderate amount of work yesterday and got through it easily. She again stated her need for temporary rest and was promised a few days' partial relief after to-day. She felt that her arm was overtaxed by the heavy work of the 8th inst., and that the thumb and fingers felt the strain. She has recovered the lost ground, however.

April 11th.—The patient was transferred to other work according to promise, except at the noon hour, when she had to take her place at the key. She felt the benefit of the rest at once and had so natural a feeling in her arm that she "rather enjoyed the sending she did at noon."

April 12th.—The patient states that her arm feels "splendid."

April 13th.—Rained to-day, consequently her arm feels slightly heavy. As circumstances prevent her from continuing the treatment, she states that a careful estimate of her arm now is that it is not equal to her early and best work, but it is fully equal to its condition nearly two years ago. The thumb and the fingers stay on the key perfectly and are as flexible as ever. The power and endurance of the whole arm are below par, although wonderfully improved.

May 8th.—Upon resuming work after stopping the treatment, her arm lost some of the gain, but soon ceased to lose and was steadily doing well; the result was very satisfactory. It is now twenty-five days since the last treatment, and she is using her arm with a very fair degree of comfort.

The points of interest about this case are that she had only fifteen electrical applications; that she was obliged to pursue her vocation during the treatment until the last three days; that her gain was even and continuous, and that the wrist, which was powerless, recovered on a par with the average strength of the entire arm. The duration of the sittings was about fifteen minutes, which was increased to twenty minutes toward the last. It was her belief and my own that another week of this treatment with rest would have completed a radical cure.

238 Macon Street.

REPORT OF

A CASE OF AMBLYOPIA EX ABUSU.

RECOVERY WITH UNUSUALLY GOOD VISION.

BY VINCENT GOMEZ, M. D.,

BROOKLYN.

A. P., aged twenty-five years, single, a native of Germany, by occupation a bartender, was first seen on December 26, 1894, giving the following history:

Ever since he can remember has never seen much with the left eye; had a convergent strabismus in this eye up to three or four years ago, which was operated upon. For the last three or four weeks he has not only been failing, but he can not possibly state when it began. He says he sees much better at night and in a dimly lighted room. In a bright light and in the daytime he has a troublesome cloud which dazzles his sight. He is a heavy consumer of tobacco and of lager beer, taking of the latter eight or ten glasses daily, and smoking seven or eight cigars through the day. How long he has indulged in this he can not say positively, but states that he has done so for a long time. Up to three weeks ago his vision in the right eye was perfect, and his eyes did not bother him in the least.
The left eye seems somewhat smaller than the right; the pupil is dilated and reacts slowly; fixes poorly; vision in the left eye equals fingers at six inches, with no improvement. The field in this eye is very greatly contracted for all colors.

Examination with the ophthalmoscope: Media clear. Disc bluish white, the outline sharply defined and somewhat pigmented. The blood-vessels are small, especially the arteries. The field in the right eye showed a central scotoma for red. Vision in this eye = $\frac{1}{20}$, with no improvement.

Objective examination shows but slight ophthalmoscopic changes. The papilla is somewhat hyperemic, but not so decidedly at the temporal half; there is a moderately marked physiological cup; but these changes are so slightly pronounced that one may say that the result of examination is negative. A diagnosis was made of amblyopia ex abuis in the right eye, and atrophy of the optic nerve in the left.

The treatment consisted first of all in abstinence from tobacco and alcoholic beverages, and the exhibition of strychnine sulphate, gr. $\frac{1}{2}$, four times daily. On January 2, 1885, I again saw the patient. V. O. D. = $\frac{1}{20}$; the hyperemia of the disc was more marked. Ordered strychnine sulphate, gr. $\frac{1}{4}$, eight times daily. On January 4th, V. O. D. = $\frac{1}{20}$; January 11th, V. O. D. = $\frac{1}{20}$; January 18th, V. O. D. = $\frac{1}{20}$; does not feel any rigidity of muscles or jaw; is still taking a fifth of a grain of strychnine daily. February 4th, V. O. D. = $\frac{1}{20}$; March 1st = $\frac{1}{20}$; has not been taking strychnine with any regularity. Ophthalmoscopic picture about the same. March 8th, V. O. D. = $\frac{1}{20}$; March 15th, V. O. D. = $\frac{1}{20}$. March 8th, V. O. D. = $\frac{1}{20}$; reduced amount of strychnine to a thirtieth of a grain, six times daily. April 1st, V. O. D. = $\frac{1}{20}$. April 8th, V. O. D. = $\frac{1}{20}$; reduced strychnine to a thirtieth of a grain, four times daily. Reads Jaeger No. 2 at six inches, a thing he has not accomplished in five months. April 15th, V. O. D. = $\frac{1}{20}$; reduced strychnine to a thirtieth of a grain, three times daily. April 21st, V. O. D. = $\frac{1}{20}$; Jaeger No. 1 at five inches. April 26th, V. O. D. = $\frac{1}{20}$; discontinued the use of strychnine. April 29th, V. O. D. = $\frac{1}{20}$; May 14th, V. O. D. = $\frac{1}{20}$; feels well. The light does not seem to dazzle his sight. Ophthalmoscopic examination reveals a normal fundus.

Amblyopia from the abuse of alcohol or tobacco has been recognized clinically for quite a long time, but not until recently understood accurately.

Uhlhoff examined 1,000 patients who were addicted to alcoholic excess (alcoholism), and out of these found six per cent. affected with amblyopia; in 6.5 per cent. he found the peculiar nerve lesion without amblyopia, and in 5.3 per cent. pathological conditions of the optic nerve and the adjacent retina. Added to these were some other lesions affecting the pupils, the muscles, and the retina, making a total of eye diseases among 1,000 patients of about 30 per cent. How long the indulgence had continued is not stated. The ophthalmoscopic finding was that in 63 per cent. there was atrophic pallor of the temporal side of the nerve, often extending below, and this lesion occurred in all the protracted cases; in 8 per cent. there was slight but distinct haziness of the nerve and the adjacent retina; in 28 per cent. there was no abnormal appearance.

The pathological lesion is atrophy succeeding to inflammation of the axial fibres of the nerve. The beginning may be at any part below the chiasm, although by preference it affects the distal or ocular portion of the nerve. With deep lesions some time is required for their manifestation at the disc; hence, in many cases, no visible sign is afforded. The symptoms are color scotoma or absolute scotoma varying in size and usually central. There may be no reduction of acuity on examination by test types, or vision may be extremely bad. The periphery is not affected. Very frequently there is a glimmering sensation; pain is not present, either spontaneously or on pressure. Commonly both eyes are symmetrically affected—a fact which distinguishes this from other intraocular affections, such as choroiditis, atrophy of the optic nerve, cataract, etc., in which the two eyes are usually affected to a different degree.

The blindness relates to both red and green, and in very rare cases to blue, just at the centre. The progress of the disease is slow, and total blindness is not common, but recovery with normal vision does not frequently occur.

No. 399 FOURTH STREET.

A CASE OF REMOVAL OF THE MIDDLE LOBE OF THE PROSTATE IN A MAN OF SEVENTY-SIX.

By EDWIN M. COX, M.D.

The case here described is not reported because of any rarity in the pathological condition or of anything out of the ordinary in the operative treatment, but on account of the great age of the patient and his good recovery.

In a hasty survey of the reported cases I have been unable to find a successful one when the patient was so old.

This patient, whom I saw with Dr. Thomas Darlington, of Kingsbridge, was a man of seventy-six, who had previously had good general health. When I saw him he had been suffering from retention of urine for over twenty-four hours, not having called a physician for some time after the onset of his symptoms, and the cause of this retention I found to be an enlarged prostate, with the enlargement, as I decided, practically confined to the middle lobe, for a rectal examination showed that the rest of the organ was only very slightly increased in size. The bladder was distended so as to reach within an inch and a half of the umbilicus, and as the patient was thin it formed an exceedingly prominent tumor. He was, of course, in great distress. This was his first serious difficulty, and he denied all forms of venereal disease. He had no signs of a urethral stricture.

It was entirely impossible to pass any instrument into the bladder through the urethra, and as I was not prepared to operate at the time, as it was late at night and the proper instruments were not at hand, I aspirated the bladder above the symphysis and withdrew nearly two pints and a half of dark, turbid, ammoniacal urine.

Next morning I performed a rapid external urethrotomy for drainage, with a view to getting the patient and his bladder into better condition for some further operative interference, which, in view of the condition which I felt sure to be present, I thought necessary, if any permanent good result was to be expected. The perineal tube was left in place for several days and it drained well, though the deposit of phosphates in it gave a little trouble. The quality of the urine became very much better, and the patient’s general condition improved.

In about a week, as the patient’s condition seemed to warrant it, I did a suprapubic cystotomy in the usual way, using
the longitudinal incision, as I wished to spare the patient as much loss of blood as possible. No rectal bag was used, but the pelvis was elevated, and no trouble was experienced in avoiding the peritoneum. The bladder wall was thicker than was to be expected, considering the distention to which it had been subjected, and was somewhat more friable than it should have been. I found the condition to be one of typical middle-lobe hypertrophy. That portion of the prostate formed a hemispherical mass about an inch in diameter, and was the evident cause of the trouble. It was soft, and evidently very vascular. The mucous membrane of the bladder was in good condition, and there was no sacculination in the walls of that organ. The offending middle lobe was not pedunculated enough to treat by ligature or excision, and I considered it to be too dangerous to attempt excision with the knife, so I destroyed with the Paquelin cautery what I thought to be enough to remove the obstruction, and packed with gauze down to the cauterized surface. This controlled the haemorrhage, which had been moderate. A suprapubic drainage-tube was introduced in addition to the packing, the perineal tube removed, and the wound in that region treated also by packing. The patient did well continuously; his temperature did not reach 101° at any time, and the wounds were treated as is usual after a suprapubic cystotomy by frequent dressings. Sounds of good size were introduced into the bladder through the urethra at regular intervals after the operation, and they entered easily. The patient's recovery was slow but steady, and now, almost a year after the operation, I am able to report him well, for such is the last word from him received about a month ago.

In view of the recent developments in the treatment of similar cases by the removal of one or both testes, apparently with such good results, and balancing against them the immediate and remote possible disadvantages of the suprapubic operation, I think that in another such case I should prefer the operation of castration to that of the radical one on the prostate. Some cases of suprapubic cystotomy do have a more or less permanently persistent fistula, and this is a very disagreeable sequela, to say the least. Furthermore, it seems to me that, granting the efficacy of the operation of castration, very few patients would weigh the disadvantages of the anorchid condition against the advantages of normal menstruation and a healthy bladder, of course taking into consideration the age at which enlargement of the prostate occurs.

45 West Thirty-ninth Street.

The Onondaga Medical Society.—The annual meeting will be held in Syracuse, N. Y., on May 16th, under the presidency of Dr. J. H. Coe. The programme includes the following titles: Drinking Water in Rural Districts, by Dr. O. G. Dibble; The Necessity for Early Recognition of Cancer of the Womb, by Dr. A. B. Miller; Prophylaxis by Sanitation, by Dr. B. F. Chase; Favus, by Dr. W. H. Dunlap; The Predisposition of Children to Lung Complications after Pertussis, Scarlet Fever, or Measles, by Dr. Frank McMarrow; and the President's Address, by Dr. J. H. Coe.

The Niagara Falls, N. Y., Academy of Medicine, recently organized, has elected officers as follows: President, Dr. G. C. Clarke; Vice-president, Dr. O. E. McCarty; secretary, Dr. F. R. McBrien; treasurer, Dr. W. R. Campbell; trustees, Dr. Talbot, Dr. Van Pelt, and Dr. Clarke.

THE NEW YORK MEDICAL JOURNAL.

A Weekly Review of Medicine.

Published by D. APPLETON & Co. Edited by FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, JUNE 1, 1895.

A MODERATE VIEW OF THE ANTITOXINE TREATMENT OF DIPHTHERIA.

In the Journal de clinique et de thérapeutique infantiles for May 16th there is an article by a well-known physician of the Hôpital Trousseau, Dr. G. Vriot, in which he says that, according to his observation, while the antitoxine treatment gives brilliant results in ordinary cases of pharyngeal diphtheria, and especially in cases in which laryngeal stenosis is the main source of danger, it fails constantly in what he calls toxic cases, those in which death is due to general poisoning, the chief effect of the poison falling upon the heart and the peripheral vessels, with a great reduction of the amount of urine excreted or its total suppression. But he reflects that the experience which had led him to this conclusion had been in hospital practice, and that children affected with this form of diphtheria are seldom or never sent into a hospital early in its course and do not usually receive the antitoxine treatment at their homes. Even this saving reflection, however, has been upset by his having recently seen the treatment fail in a case in which he was able to employ it from the outset of the disease. He gives the history of this case and of fifteen other fatal cases.

Save in a few exceptional instances, says M. Vriot, where death takes place with lightning rapidity, the powerful action of the serum in the way of opposing membranous exudation suffices to relieve the throat. The glandular swelling and the infiltration of the neck are reduced, the general condition is ameliorated for the time being, and the child takes food and regains its vivacity. But this is a deceptive remission; at the end of two or three days the face becomes pale, general prostration supervenes, and the pulse intermits and then is altogether imperceptible. This pulselessness often persists for two or three days before death occurs, although the heart, of course, keeps on beating to the last. The limbs are cold, but not cyanotic, and M. Vriot says that certain features of the child's condition remind one of the algid phase of Asiatic cholera.

Nevertheless, he says in conclusion, we should not be discouraged or underrate the immense value of the antitoxine treatment. If it is useless in these toxic cases, even when employed from the start, it yet has the precious property of causing the false membranes to disappear even in the gravest cases; the enormous reduction of the mortality from diphtheria is incontestably due to the rapid casting off of the exudate caused by the serum. The phenomena of laryngeal obstruction do not persist after the injections; the action of steam generally suffices to relieve the remnants of them, temporary intubation, for two or three days, wards off suffocation in the few cases that
call for it, and tracheotomy, at least in hospital practice, is destined to grow rarer and rarer.

Finally, M. Variot questions the antitoxic action of the serum. If, he says, it were really antitoxic, it would be strange that its antitoxic action should cease to be manifest in the very cases where it was most necessary. It certainly counteracts the formation of false membranes, but its antitoxic power is extremely doubtful, at least when the disease is actually developed. Not only does it fail to prevent death in the toxic forms properly so called, but it does not avert the partial paralyses of convalescence, which are themselves only mitigated toxic manifestations.

MINOR PARAGRAPHS.

AN UNLICENSED PRACTITIONER IN YONKERS.

A MAN named Waring, who has at various times and in different places been in trouble as the result of dishonest and criminal practices, and once served a term of imprisonment for practising without registration, has been incarcerated in Yonkers. The prosecutor was Dr. E. M. Morrell, of Yonkers, and the community of that city owe Dr. Morrell a debt of gratitude for ridding them, for the time being at least, of a very dangerous person. It seems that Waring has twice been on trial for manslaughter, and escaped conviction only by lack of convincing evidence, and that his career of infamy includes the personation of a benefactor whose diploma he had stolen. Dr. Morrell feels confident that when the man’s present sentence expires he can prove charges against him sufficient to send him to Sing Sing for a term of years.

M. PASTEUR AND FRANCO-PRUSSIAN ANTIPATHY.

It is to be hoped that a statement lately made in one of the French newspapers, the Figaro, will turn out to have been unfounded. It is to the effect that the German Emperor, having taken means to ascertain whether the great French chemist would accept a decoration from the German government, received the reply that he could not, for he could not forget 1870. Surely such resentment is unworthy of M. Pasteur, and there fore we question the accuracy of the statement.

THE AMERICAN SURGICAL ASSOCIATION.

This year’s meeting, in New York, now drawing to a close as we go to press, has been exceedingly profitable and satisfactory. The president, Dr. Dennis, loyally assisted by the other surgeons of New York, has been able to supplement the reading of papers and the discussions by a very thorough exposition of the details of hospital surgery as practised here and by social entertainments that seem to have been very acceptable to the members from other parts of the country.

JUSTICE TO A NEW YORK SURGEON.

Is a recent number of the Progrès médical there is a report of a meeting of the Société de chirurgie whereat there was reported a case of removal of a calculus from the ductus cholecysticus communis. The tenor of the report is such as to lead the editor of the Progrès to append a foot-note intimating that it does not seem to be known to the members of the society who was the first to remove such a calculus from the living subject, and informing them that it was Dr. McBurney, of New York.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending May 28, 1895:

The Mississippi Valley Medical Association.—The twenty-first annual meeting will be held in Detroit on September 3rd, 4th, 5th, and 6th. The chairman of the committee of arrangements, Dr. H. O. Walker, of Detroit, thinks there is the prospect of a large attendance. It is probable that arrangements similar to those of last year will be effected in the matter of railroad rates—namely, one fare for the round trip. Dr. William Pepper, of Philadelphia, is to deliver the annual address in medicine.

Changes of Address.—Dr. Samuel M. Brickner, to No. 109 West Eighty-second Street, New York; Dr. W. Gilman Thompson, to No. 34 East Thirty-first Street, New York.

Society Meetings for the Coming Week:

MONDAY, June 3d: New Hampshire Medical Society (first day— Concord); New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; New York Medico-surgical Society; Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Niagara Falls, N. Y., Academy of Medicine; Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Alans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, June 4th: Indian Territory Medical Association (first day—South McAlester); New Hampshire Medical Society (second day); New York Neurological Society; Buffalo Medical and Surgical Association; Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Columbus (semi-annual—Chatham), Franklin (semi-annual), Herkimer (quarterly—Herkimer), Niagara (annual—Lockport), Saratoga (annual), and Yates (annual), N. Y.; Hudson and Warren (annual), N. J., County Medical Societies; Androsceggin, Me., County Medical Association ( Lewiston); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

WEDNESDAY, June 5th: Ontario Medical Association (first day—Toronto); Maine Medical Association (first day—Portland); State Medical Society of Wisconsin (first day—West Superior); Indian Territory Medical Association (second day); New York Academy of Medicine (Section in Public Health); Society of Alumni of Bellevue Hospital, New York; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.
DEATHS.—

Thursday, June 6th: Rhode Island Medical Society (Providence); Ontario Medical Association (second day); Maine Medical Association (second day); State Medical Society of Wisconsin (second day); New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medical-psycho logical Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington); Cuyahoga, O., County Medical Society.
Friday, June 7th: Maine Medical Association (third day); State Medical Society of Wisconsin (third day); Baltimore Clinical Society.
Saturday, June 8th: Obstetrical Society of Boston (private).

Births, Marriages, and Deaths.

Died.

Hawkes.—In New York, on Saturday, May 25th, Dr. John Marshall Hawkes.
Law.—In Brooklyn, on Saturday, May 25th, Dr. George E. Law, aged thirty-four years.

Book Notices.

"No young practitioner can be regarded as thoroughly equipped for surgical work who is not both a good pathologist and an expert bacteriologist. The confidence born of a knowledge of pathogy and bacteriology enables him to assume grave responsibilities and grapple successfully with the most complicated problems. It is from men thus equipped that we have a right to hope that the future masters of surgery are to be evolved."

These words, taken from the preface to Dr. Warren’s book, happily express what every modern surgeon feels with regard to the importance of a knowledge of pathology and bacteriology in surgical practice.

The progress of surgical pathology has been so rapid in the past few years that books of a decade since give us no idea whatever of the modern views, and bacteriology has so modified our handling of diseases that only those who are familiar with the latest literature and practices can be said to do full justice to their patients. Since Billroth’s Surgical Pathology, no book has appeared to take the place in relation to modern surgery which it held in its day, until the present volume. Works upon pathology and bacteriology are numerous, but they are written for the laboratory. The present volume is for the bedside, the amphitheatre, and the ward. It deals with things not as we see them through the microscope alone, but as the practitioner sees their effects in his patients; not only as they appear in and affect culture media, but also as they influence the human body; and, following up these demonstrations of the nature of diseases, the author points out the logical treatment of them. This is indeed the practical end, the only end worth striving for, to cure the ills that flesh is heir to, or circumscribe and prevent their progress.

The book begins with a résumé of bacteriology in general, but soon enters upon the special field of surgical bacteria. In this chapter the different organisms which cause or influence surgical diseases are clearly and succinctly described. These bacterial forms are not numerous, and it will require no great outlay of time for the surgeon to familiarize himself with them and the means of finding them. They are all illustrated in this chapter by colored plates which show the proper staining for their best examination. These plates are works of art, and the publishers are to be congratulated upon their production.

The distinctions between simple and infective inflammation are well brought out. Under the latter heading the chapter on acute osteomyelitis is one of the most opportune in the book. The importance of early recognition and radical interference cannot be too strongly urged, and the practical points thrown out by the author with regard to detecting the situation and removing the original focus of the disease are well worth remembering.

While points for criticism may be found in the book, and differences of opinion, especially with regard to therapeutics, will arise as we read it, the author is so logical and so ready with a reason for the faith that is in him that we are often convinced against our own experience. The chapter on aseptic and antiseptic surgery is interesting historically as well as suggestive. One reared in the modern school and hospital can hardly imagine the horrible condition of the French hospitals here described, but quotations from their own surgeons prove it to exist.

The last chapter, or appendix, is devoted to serum therapy. The author has had little experience with it, and neither endorses nor condemns it. As to diphtheria antitoxine, he has nothing whatever to say, preferring, no doubt, like many others, to await the sober judgment of larger experience.

The appearance of this work is timely. The profession were in need of such a book, and we are proud that it has come from one of our own countrymen. It should be in the hands of every surgeon and in the curriculum of every medical college.

Ten years since it was almost a daily occurrence for the traveler in our metropolitan street cars to find himself sitting next to a sufferer from the so-called "frett running ear," and a more disagreeable seat can hardly be imagined. To day we rarely see one. If otology had done nothing else but relieve the sufferers and society of this loathsome affection, it would have deserved our lasting praise and gratitude. The present work, however, compared with those of earlier dates upon this subject, shows what a marked advance this specialty has made. The application of science and mechanics to the examination and treatment of diseases of the ear is second only to their use in those of the eye, and the modern operations in the middle ear require a delicacy and precision equal to, if not exceeding, those of the oculists. While describing in sufficient detail these difficult procedures and scientific application of mechanics to the ear, the author has sought to present the subject to the student and general practitioner rather than the specialist, that they, seeing these cases in their early stages, may by proper attention prevent the later and more obstante diseases of the ear. It is a book, then, for the whole profession, and no one will be disappointed who reads it.

To review the chapters seriatim would be a pleasure, but of little profit to our readers.
BOOK NOTICES.

The sections upon examination, especially that upon the functional examination of the ear, are replete with modern and practical suggestions. The minuteness and care with which these manipulations are detailed might appear somewhat prolix to the specialist who already understands them, but to the reader, who must learn them from the books or not at all, they will be of great assistance.

The author’s warning against ordering patients to instil a few drops of an alkaline solution into the ear in order to soften impacted cerumen is timely and wise, no doubt, but he will have difficulty in persuading the general practitioner who has syringed in vain for half an hour, then ordered borax and olive oil instilled for twenty-four hours and at the end of this time removed the impacted mass without pain by one or two syringe-fulls of warm water, that the practice is pernicious. Cleaning the ear out at one sitting and thoroughly examining it is undoubtedly the scientific and rational method, but the instruments and skill requisite for this are often wanting, and the old plan is not likely to do so much harm as harsh and awkward handling of a tender ear.

The author is an advocate of operations upon the middle ear—tendonotomy, osteotomy, stapledectomy, euretting, etc.—and certainly with his skill and experience he is justified in undertaking them. They are operations, however, for the expert specialist, dangerous even at his hands, and should not be undertaken by the ordinary operator, however simply and clearly the author describes them.

The relationship between affections of the ear and general diseases forms an important chapter, especially to the family physician. Pathology and pathological theories form a very small portion of the book, though they are not slighted. The work is a thorough practical review of the subject, and will take a high place in its literature.

The mechanical and artistic features of the book are worthy of special mention, for both author and publisher may feel justly proud of their production.

The International Medical Annual is the American edition of the Medical Annual, and of the latter there has so recently appeared a review in this journal that it remains but to point out the identity of the two books and to repeat that “it is one of the most useful books with which we are acquainted.”

This is the eleventh issue of the Year Book of Treatment. It is also the best, not because the others have not been good, but because the publication each year approaches a little nearer perfection. Several editorial changes have been made in this issue, Dr. Coupland having assumed charge of the section on Diseases of the Heart and Circulation, Mr. William Rose taking the section on General Surgery, and Dr. Whitelegg that on Public Health and Hygiene. The section on Bacteriology has been omitted. The object of this book has been kept clearly in view by the editor and contributors, and in its well-selected matter, in its excellent arrangement and classification, in its several indices, and in its conveniently small size the book can not but be useful to “the busy practitioner who wishes, with a minimum of trouble, to keep himself abreast of progress in all that relates to the treatment of disease.”

MISCELLANY.

An Action against a Dublin Doctor.—Kingstown, Ireland, May 15th.—A very interesting case took place in the Court of Exchequer on the 13th and 14th inst, before Mr. Justice Murphy and a special jury. The action has been brought against Dr. John E. Hadden, of Castletown Avenue, Rathmines, by the plaintiff, Mr. Andrew Mason, of 54a Rathmines Road, carrying on business as a draper. The action has been brought to recover damages for having "negligently, improperly, and unskillfully diagnosed as small-pox" a disease which was not small-pox, but, on the contrary, erythema nodosum, for having the patient, a young girl named Maria Hawkins, in the plaintiff's employment, removed to Cork Street Hospital, and for having under the Infectious Diseases (Notification) Act reported the case to the municipal authorities of Rathmines as a case of small-pox, to the injury of plaintiff's business.

The case stands briefly thus: Dr. John E. Hadden is a bachelor of medicine and a bachelor of surgery of the Dublin University. He had attended Mr. Mason's family for the past six years. In December last he vaccinated Mr. Mason's assistants' including the girl Maria Hawkins. On the 10th of the same month he was sent for to visit the girl. She was in bed in a room at the back part of the house, in which he was told some eight girls usually slept. He made a very careful examination, lasting at least half an hour. The girl had a rapid pulse and a very hot feeling. Her temperature was 103° and on her forehead there were several raised papules. The tongue was foul and the breath objectionable. She complained of pains in her back and legs and of severe headache. He found on her limbs symptoms of erythema nodosum. The symptoms distinct from the latter were symptoms of small-pox. Dr. Hadden came to the conclusion that she was suffering from small-pox subdued by vaccination. He told Mr. Mason and recommended the girl's removal to hospital, and she was removed the following day to hospital. Dr. Day, the resident medical officer, diagnosed the case there, not as one of small-pox, but of erythema nodosum with complications. The moment Dr. Hadden heard that the girl was not suffering from small-pox he offered to give Mr. Mason every opportunity of having the mistake rectified as far as possible, but Mr. Mason would not accept that offer.

Dr. James Little, in the course of examination, said he had had considerable experience of small-pox during the epidemic of 1879. The symptoms described in court would in his opinion certainly lead to the belief that the case was one of small-pox. Having regard to what he had heard, he would not have allowed the girl to remain in the house for an hour longer than necessary. After the evidence had been concluded the jury retired, at three minutes to five o'clock, and at eight minutes to six o'clock found the plaintiff damages in £100.

In to-day's Irish Times letters have appeared from well-known medical men, all condemning the verdict made by the jury. One writer says "he trusts the Medical Press and other medical journals will organize a fund in order that the medical profession may have an opportunity of practically showing their sympathy by handing him a check to cover the damages and other expenses connected with this lawsuit."

Deformities following Fracture of Bone Shafts, with Observations on the Treatment.—At the recent meeting of the American Medical Association Dr. Thomas H. Manley, of New York, read a paper before the Section in General Surgery in which he said that, of all the serious traumatisms of the body, fractures of the long bones were the commonest. The simple and uncomplicated ones were rarely attended with danger, and, owing to the aids which modern science had placed within our reach, even those of the gravest character might generally be treated successfully if the main vascular channels had escaped injury. In adults, however, perfect restitution of the osseous structure was seldom secured, and probably in the majority of cases deformities of varying degrees followed in spite of any treatment that might be adopted.

Deformity depended, he said, chiefly on two conditions: Something inherent in the patient, and the nature of the fracture. Fracture of a single bone in the forearm or in the leg, away from the articulations, if treated on rational surgical principles, would result in a fair restoration of contour and symmetry. But when both bones of the forearm were completely fractured; when the fracture involved a joint or was accompanied with a subluxation, diastasis, or impaction; when there was a fracture through the humeral condyles into the elbow joint, through the humerus, or through the femur, the question arose, Could we always prevent deformity? Dr. Manley's experience inclined him to believe that in a large number of cases of this kind, after repair was more or less complete, visible imperfection remained. Shortening was really a type of deformity, as it was always attended with an overriding or deflection of the fragments. When an extensive shattering or disorderization of the bone was followed by excessive callus, an anular hyperostosis might occur to such an extent as to leave a distinct bump at the site of injury. At the ankle joint, after severe osteo-arthritis traumaticum, the indelible stamp of the fracture so graphically described by Pott pointed with certainty to a peculiar quality of injury long after osseous repair. The compensatory efforts of Nature, in a large measure, secured to the patient a fair degree of functional restoration, but an unmistakable deformity remained. In many cases, however, gross distortion with loss of function implied unskillfulness or neglect.

Dr. Manley classified the non-preventable causes of deformity as those dependent on extrinsic circumstances, and those which followed in consequence of organic pathological conditions. The indications for treatment in average cases were quite simple from a mechanical standpoint, but, he said, there were living tissues to be dealt with, and the question was how to preserve the vitality of the limb and secure osseous repair without disturbing the reposition of the fragments. Fractures of the femur in young children, who were habitually restless, sometimes resulted unsatisfactorily; also in heavy persons past middle life such fractures could not generally be treated successfully. Confinement in bed was badly borne by many patients, and in some cases it was necessary to get them out of bed in order to save their general health, even at the cost of a somewhat deformed limb. In some of the worst cases of fracture that were met with there might be such serious internal injuries that the bone lesion became practically of minor importance, and it might become imperative to direct our attention to the general health rather than to the bone lesion. Under certain circumstances varying degrees of distortion might occur in cases where the attending physician was unable to procure proper mechanical appliances or careful nursing.

Deformities, said Dr. Manley, due to organic imperfections in osseous structures were, owing to their nature, quite beyond our power to prevent, although with few exceptions they might generally be rectified by means of constitutional and local measures. Rickets, struma, scurvy, morasias or any other constitutional disease attended with malnutrition might interfere with prompt osseous union or so retard it that the
ments, lacking in nutrition or muscular support, might deviate before consolidation was complete. There was another pathological condition, said the author, the real nature of which still remained a mystery, in which the regenerative processes after fracture were quite in abeyance, and this condition was present at all periods of life in both sexes, and in the heart and vigorous as well as in the frail and anemic. In a number of cases which had come under Dr. Manley’s observation he had noted a tendency to a bowing or deflection of the limb over the callus long after the period when union should have been complete, and many of the worst cases of deformity of the femur that he had seen had followed this condition.

In cases of delayed union or non-union in young, vigorous persons a complete change of diet, the readjustment of the limb, moving the patient, free motion, massage over the point of fracture, and—in cases of non-union of the bones of legs—changing the posture of the body from the horizontal to the upright, might give such a sudden impetus to regenerative processes that, unless great care was exercised, the fragments might suddenly become fixed in a distorted direction. Distortion was more serious, said the author, when it occurred in the legs, although it could be readily corrected by the application of splints, and, if at the elbow or at the wrist were excluded, they must be regarded as being comparatively rare. Possibly this might be explained by the ground that fractures through the arm and forearm were less frequent than those through the femur and tibia. As the breaking and displacement of a bone depended on the action of physical forces, it was obvious that it was only by a correct knowledge of the manner in which these acted, and, afterward, by making use of them in various ways, that replacement or rectification was possible, until the natural processes came to the aid, consolidated the fragments, and restored symmetry to the fractured shaft.

In the treatment of fractures in general the first aim should be to prevent deformity or to so minimize it that it would not seriously affect the function of the limb or impair its normal contour. Among the aids of fundamental importance in the treatment of fractures, rest, relaxation, and support occupied an advanced rank. The idea, said Dr. Manley, that attention must be concentrated exclusively on the shattered bone was an erroneous one, as the bone in the bone—shaft was a passive organ and subordinate to muscular action. The mangled muscles and contused nerves and blood-vessels needed repair as much as the bone; indeed, to their integrity we must look for osseous regeneration. Therefore, in order to secure to the lacerated tissues the necessary rest, we should begin by relaxing the most powerful set of muscles in the limb. With muscular relaxation, resolution of traumatic inflammation, and relief from muscular spasm, the broken bones fell into place, for the innate tendency of fractured bones was to fall into their natural position. Pulling and dragging on the muscles, forcible extension and counter-extension, so generally practised at the present day, would not force muscles into relaxation, but rather provoke them into further and more stubborn resistance.

Splints were but auxiliaries, for they fixed nothing; they only supported. The moment they were applied on the theory of mechanical compression we erred, and were soon reminded of it by severe pain, muscular contraction, or sloughs. Great care should be exercised while splints were in use; in many cases they should be changed frequently, or the seat of fracture inspected, so that any displacement might be corrected. It was well to remember, Dr. Manley said, that the period of time necessary to effect osseous repair was extremely variable. When perfect replacement of the fragments took place and there was only slight injury of the soft parts, union was almost immediate without callus formation; but in many cases union was extremely tardy and imperfect. During the transition stage the nescent bone was passing from a ligamentous condition to that of ossification, and while the new connecting segment was elastic and pliant we should assure ourselves that any tendency to bowing of the shaft was corrected, and a uniform support should be continued until consolidation was complete. Neglect to observe this precaution resulted in many a distorted limb. The tendency of a fractured limb to shrink and wriggle about under any solid, impermeable plaster-of-Paris shield constituted the greatest objection to this mode of dressing, which, theoretically, he said, would seem to be the ideal one, but many deformities had followed its use, and for this reason the author never employed it until all tumefaction had subsided and primary adhesion was complete.

In regard to proper surgical procedures in overcoming osseous distortions, Dr. Manley said that osteotomy was a means of the greatest value in the fractures of children. Osteothesis was also an important aid in the treatment of fractures of the smaller shafts in young subjects during the earlier stages of ossification. Judiciously employed, it had a large field, and in experienced hands was of great value. When this was not appropriate or failed, we might resort to osteotomy or, more strictly speaking, to osteotomy preliminary to osteosynthesis. Modern advances in medical science, said the author, rendered section through living bone a safer procedure now than formerly, but it should not be practised promiscuously or with impunity, for when performed under any other than extreme circumstances it became a most reprehensible undertaking. Osteotomy was often full of peril, both to the life of the patient and to the integrity of the limb. The osseous substance was exquisitely sensitive to and intolerant of mechanical interference or atmospheric irritation, and, if by any prophylaxis this could be entirely overcome, we might then proclaim that the difficulty of dealing with osseous deformities following fractures was solved. In other bones than the femur we might secure fairly good results with osteotomy. In several cases in the author’s practice it had served an admirable purpose when the tibia or the ulna had been involved. In these cases, he said, it was sufficient to partly divide one bone and then fracture its fellow. In the leg it would usually be found that the fibula would give way after the tibia had been pressed into place. It was safer, however, not to advise osteotomy unless the distortion was so great as to seriously diminish the functional power of the limb, or it was a source of constant pain to the patient.

Osteotomy, like osteotomy, said Dr. Manley, was always a formidable undertaking as a corrective measure in fracture deformities. It ranked in the same class as a major amputation, for more or less violence was done to the entire limb.

In a certain number of cases of deformity that involved the articulations it might be necessary to practise tenotomy, division of the soft parts, or such measures as would assist us in procuring correction or restitution of function. For most types of osseous articular deformities, operative interference promised very little in the way of securing full restoration of function or improvement in appearance. Various efforts had been made in this direction, but, except in elbow fracture, very little progress had been made.

It might be said that, while the correction of deformities occupied an important place in operative and orthopedic surgery, and while, with the aids which modern science had placed within our reach, we might secure results hitherto quite impossible, yet this, like the prevention of deformities, had its limitations. It might be said that with certain elements of the osseous structures, in certain bones, in the young and healthy, very much might be hoped for and accomplished. Our line of ac-
tion should be by those methods which would not require the application of great force, or were accompanied with extensive mutilation, or endangered the vitality of the limb.

The Education of Neurotic Children.—The Hospital for April 27th publishes an article on this subject in which the writer refers to a course of lectures recently delivered by Dr. Blandford on the Diagnosis, Prognosis, and Prophylaxis of Insanity. Dr. Blandford, says the writer, insists upon the great and preponderating influence of heredity in the production of insanity. He also points out that the true prophylaxis of insanity is to be found in the proper regulation of marriage. Many, he says, have hoped that legislation would some day interfere to prevent marriages between persons with neurotic tendencies. But such hopes are chimerical, as we may judge, says the writer, from the fact that so far legislation will not even annul the bond which ties a man or a woman to a partner, perhaps quite young, who is hopelessly insane and who may remain so for the remainder of a long life. It is necessary, then, he says, to turn to the practical and to consider what may be done to preserve the mental health of those who are born with a tendency to mental deficiency or disease.

In early days plenty of food and sleep and careful guarding from all causes of nerve disturbance are to be insured, for it is difficult to exaggerate the evil that may be done to a nervous child by the tales of ghosts, robbers, bogies, etc., with which many children are continually indulged. The inculcation of the precepts of religion also too often becomes themeans by which terrifying ideas are implanted in the infant mind, much to the disturbance of that peacefulness during the hours of rest which is essential to its normal development. It is pitiful, says the writer, to think of the number of children who look forward to bedtime as a time of terror, bury their faces in the bedclothes, and only when exhausted fall asleep haunted by visions of a constant all seeing eye, by dread of unending torments for each unforgiven, perhaps forgotten, little fault, and by fear of lightning and other natural phenomena which they have been taught are instruments of wrath. From all such thoughts the developing brain should be protected. Later on, when education, as it is now understood, begins, the child among whose ancestors neuroses have prevailed requires even more protection, for every influence is often brought to bear to disturb his mental equilibrium. If he is dull and backward he is punished, if he is bright, intelligent, and precocious he becomes the pride of his teachers and is set to win scholarships for the glory of his school. In either case, says the writer, he is exposed to the very turmoil of mind from which he should be most protected.

In the choice of a profession the young man is beset by the terrors and evils of competitive examinations. This brings us, says the writer, to one of the most important points in the prevention of insanity in those predisposed to it—that is, the fitting of the work of life to the capacity of the individual. The ambitions of the parents, combined with the ill-regulated hopes and desires of the son, often drive the latter to undertake responsibilities for which he is by no means fitted, and thus cause a nervous breakdown which could have been avoided. Dr. Blandford says that "it is not difficult to point out the occupations which are unsuited to such a man; it is more difficult to say what is the most suitable. That will be best which entails the least worry and responsibility, which does not involve money losses or great and sudden disappointments." But, says the writer, what sort of a life is this, where is it to be found, and who is to impose it on young men who are often of exceptional brilliancy and precocity? So far as the digulards are concerned, he says, parents should not push them, but accept the fact that they are mentally ill developed and avoid placing them in positions involving responsibility and care. This is a blow to the father's pride, but the son will accept his lot. But the brilliant scion of a neurotic or of an insane family is not so easily dealt with, for at twenty-one he is his own master. It is all the more necessary, then, says the writer, that care should be taken in the early training of those whose family history shows any taint of insanity, and that careful regulation of the mode of life upon which the prophylaxis of insanity depends falls upon the man who has received a heritage of instability of mind, and who may be difficult to control or to persuade.

False Whooping-cough Produced by a Foreign Body in the Larynx.—In the Journal de clinique et de thérapeutique infantiles for April 25th M. de Pradel relates the following case:

The patient, a child, five years old, had swallowed a small stone. An examination of the throat and of the larynx gave no results, and the author concluded that the stone had gone into the stomach. On the following day he was again called to see the child, who, the mother said, had had an attack of coughing during the night. After a careful examination the author could find nothing to support the mother's statement; moreover, the general condition did not warrant such a diagnosis. The symptoms pointed rather to an attack of the stridulous laryngitis so frequent at that age, and M. de Pradel ordered an appropriate treatment. For about ten days very violent fits of coughing, which were accompanied with vomiting, continued and the parents, being somewhat in doubt as to whether the stone had gone into the stomach or not, took the child to the Hopital de l'Enfant-Jesus, where a consultation was held, from which, however, no successful results were obtained, as the mother absolutely refused to allow the child's throat to be examined in any way. During the consultation the patient was taken with a violent fit of coughing, and the diagnosis of whooping-cough was made. For two months the disease ran its regular course without increasing, but also without diminution of the attacks of coughing, which occurred day and night and were accompanied by absolutely characteristic slimy vomitings. At the end of that time another consultation was held, the former diagnosis was maintained, and the following prescription was ordered: Tincture of aconite root and tincture of belladonna, each, seventy-five grains. Five drops of this were given every night and morning, each dose being increased by one drop every two days until twenty drops were given every day. Friction over the back with oil of turpentine was also employed.

In spite of this treatment the whooping-cough persisted, when one day, more than four months after the first attack of coughing, while the child was playing rather roughly with its father, it was taken with a violent fit of coughing and vomiting, during which it brought up a small stone. The stone weighed exactly twelve grains and measured thirteen millimetres and a half in length, eight in width, and four in thickness. That this stone had remained in the larynx during the entire period of the "whooping-cough," says M. de Pradel, there is not the slightest doubt. The onset of the cough immediately after the stone had been swallowed and its sudden and complete cessation after the expulsion of the stone leave no doubt whatever on the subject.

If it is necessary to determine the anatomical and exact region of the larynx where the stone had lodged, it must be conceded, says the author, that it could have been only in the ventricle of the larynx; its difficult and long-delayed expulsion indicated that it had been held there in a rigid position owing to its size and the anatomical arrangement of that region. Is not the fact, asks M. de Pradel, that a foreign body lodging in the ventricle of the larynx and producing by its presence alone an irritation of the ventricle, a hyperaemia of the ventricular
mucous membrane, and an abnormal mucous secretion, sufficient to explain the attacks of "whooping-cough" and to confirm the theories of Bevan, of Gendrini, and of Niemeyer, who assigned as a cause of this disease a simple estarrh of the respiratory mucous membrane? Would it not be equally logical to admit, he asks, with Trouseau, Roger, and Bonchut, who designated whooping-cough as a catarrh with neurosis, that the irritation produced by a foreign body of the ends of the laryngeal nerves might cause attacks of coughing by extending the excitation of these nerves to the pneumogastric nerve?

For many years, says the author, the parasitic theory in regard to whooping-cough has been asserted by many authors, among whom Ritter described a micro-organism pathogenic of whooping-cough, which he found in the tracheal mucus, with which he obtained pure cultures of a diplococcus. This was inoculated in dogs and caused violent attacks of coughing.

In the foregoing case the author noted an important point: During the four months that the disease ran its course a brother and sister of the patient slept in the same room with him and did not take the disease. This single clinical fact seems to indicate clearly, he thinks, that the child did not have true whooping-cough, or that there exist two kinds, one proceeding from a mechanical and individual irritation and not transmissible, and the other from a micro-organism—the diplococcus of Ritter, for example—and contagious.

If the cause of the whooping-cough that was observed in this case was beyond doubt and it should be unrepressed attributed to the presence of the stone in the ventricle of the larynx, there is a conclusion which we may draw from this fact, says M. de Pradel, and that is, that when a foreign body has been "swallowed" a careful examination of the larynx should be made.

**Fat in Pulmonary Consumption**—At a recent meeting of the Pennsylvania State Medical Society Dr. Thomas J. Mays, of Philadelphia, read a paper on this subject in which he remarked that fat was one of the most important, though one of the most unstable, constituents of the human body. It gave weight, rounded off the angular outlines, and protected against cold and injuries. Normally, it fluctuated with the cycle of the seasons, diminished rapidly in disease, and speedily returned during convalescence. Its diminution marked one of the earliest symptoms of pulmonary consumption, hence the index which was afforded by the weighing scales formed an element of precision in the diagnosis and prognosis of this disease.

The fat of the body, he said, was contained in cells which were composed of protoplasm and possessed nuclei. The cells abounded in the interstices of loose connective tissue, and were found under the skin, especially in the soles of the feet, in the palms of the hand, in the buttocks, in the mammary glands in women, around the synovial capsules of the joints, in the orbits, in the medullary canals of bones, in the surroundings of the kidneys and the omentum, and on the surface of the heart.

When an animal fattened it appeared that oil globules were formed within the fat-cells. These globules increased in number while the protoplasm of the cell diminished. These globules were not deposited in the cells in a mere mechanical manner, but they were formed by the cell itself and at the expense of its own protoplasm, which became very much attenuated. It seemed, therefore, that the fat of the body was as much a secretion of the fat-cells as pepsin was a secretion of the peptic glands, or as the oily matter of the skin was the secretion of the sebaceous glands, or as the fat of milk was the product of the cells of the mammary gland.

From the fact that the protoplasm of the fat-cells underwent metamorphosis when the oil globules formed, it seemed quite obvious that other than fatty food was used by the body in the formation of fat, and that in all probability proteid or albuminous food was used for this purpose. It had been shown by Liebig long ago, said Dr. Mays, that fatty, starkey, and saccharine foods did not form the exclusive supply of fat in the body; for the butter in the milk of a cow far exceeded the scanty supply of fat in her food, and the wax which was produced by bees was out of all proportion to the amount of sugar which they consumed in their food. The feeding experiments of Laws and Gilbert also demonstrated that for every hundred parts of fat in the food of fattened pigs four hundred and seventy-two parts were stored up as fat, showing, therefore, that fatty foods supplied only about one fourth of the fat which was contained in the body.

That proteids formed an important source of fat in the body, he said, was shown by the following facts: Microscopic observation showed that the fat of milk was formed by the epithelial cells of the mammary gland through the probable metabolism of protoplasm. Fat in milk was largely increased by albuminous and diminished by fatty foods. When cheese ripened its proteids were converted into fat. Milk sugar was maintained in abundance in the milk of carnivora even when fed on an exclusive meat diet (Foster). Fatty degeneration, as was often witnessed in the heart and in other important organs, was further evidence that proteid substances were converted into fat.

Dr. Mays said that he did not wish to convey the idea that albuminous foods supplied the greatest part of the fat of the body; we knew that this was done by the carbohydrates; but he laid special emphasis on the fact that fats and oils did not play the important part which they were popularly supposed to do in the nutrition of the animal body, also on the fact that proteids were of greater value as fat-producers in pulmonary consumption than they were generally believed to be. In fact, he said, evidence was not wanting to show, as had already been limited at, that both fats and carbohydrates diminished the metabolism of the body, while a meat diet enhanced the same, increased the oxidizing activity of the body, multiplied the number of red blood-corpses, and led to a rapid consumption of fatty and carbohydrate food. A great deal of harm had followed the doctrine that the fat of the body came only from the fat of the food, and that therefore the only way to fatten a consumptive was to ply him with fats and oils of various descriptions. Every experienced physician knew, said Dr. Mays, that oil and fats produced dyspepsia in many such patients, and did no good in some with whose digestion they seemed to agree, while there were a few who did well under their use, but whose fat did not seem to have any staying qualities. It seemed to him that oily and fatty foods conferred a real benefit only on a minority of consumptive sufferers, and that much greater service was rendered to the nutrition of such patients by the administration of albuminous foods, the important ones among which were freshly expressed beef juice, beef, nutton, lamb, milk, eggs, oysters, clams, liquid peptondoids, beef powder, meat juice, beef-potatoes, etc.

An important question came up here, said the author, in regard to the influence which rest and exercise had on the fattening process of the human body. Was physical activity more conducive to fat-building than rest, or was it not? This might be said to depend altogether on circumstances. There was no doubt that in health exercise gave both fat and strength, but it was quite different with the invalid. The fat which was stored up in health represented so much surplus capital which was laid up for a rainy day; but the consumptive had no surplus capital and lived, as it were, from hand to mouth. All his energies were devoted to the maintenance of those bodily functions
which were immediately necessary to life—such as circulation, respiration, digestion, innervation, etc.—and very frequently these were carried on imperfectly. To him, therefore, exercise was meaningless, for he had no capital to exercise on until he got stronger and laid up some. Hence he must practise economy. He must restrict his outgo and increase his income. This he could do only by resting.

The author had frequently observed that, with no other change in the treatment than the substitution of rest for exercise, consumptives showed a marked and distinctive improvement and gain in flesh.

It was also of great interest in this connection to consider the influence of the nervous system on nutrition. Whether there were special trophic nerve fibres or not, it was quite clear from the large number of experiments which had been performed that the nutrition of that part of the body suffered whose supplying nerve was divided or injured. Clinical evidence pointed out the same. It was well known that in neuralgia, the limbs, or area of tissue to which the affected nerve was distributed, became emaciated and lost its fat. Clouston, said Dr. Mays, stated (Mental Diseases, p. 469) that thinness was the almost constant accompaniment of melancholia, and that fattening of the patient was its natural cure; also that this deprived or weakened trophic energy speedily tended to end in phthisis pulmonalis. In fact, he believed that melancholia had a special proneness to terminate in pulmonary consumption. Phthisis and melancholia ran a parallel course in this respect. Could we not discern in this, he asked, a confirmation of the view that a causative relation existed between disease of the nervous system and disorder of nutrition? Was it not probable from this that the building of fat was intimately dependent on the integrity of the nervous system? This probability was strongly confirmed by the therapeutic action of strychnine. It was well known that this agent had no other influence than that which it exerted on the nervous system, and yet Dr. Mays said that he knew of no other single drug under the administration of which consumptives fattened more promptly than under strychnine when it was given in gradually increased doses and combined with suitable rest and nutritious food.

While it was true that increase of flesh was always desirable in the treatment of pulmonary consumption, it was a mistake to hold that every patient of this kind must make a prodigious gain before recovery could set in. He believed that women were less inclined to gain than men, and had known women make an uninterrupted recovery without increasing in weight.

In summing up the principal points, he said, it appeared that the fat of the body was made out of carbohydrates, proteins, and fats; that for fattening purposes proteins and carbohydrates were superior to fats and oils; that the latter were overrated in the treatment of pulmonary consumption; that carbohydrates and fats hindered and protid foods accelerated metabolism; that rest of the invalid promoted the formation of fat, and that exercise retarded it; that in all probability the production of fat in the body was largely under the control of the nervous system; and that strychnine, through its stimulant action on the nervous system, fattened the consumptive, and increased the number of his blood-corpuscles.

Ichthyol in Pissure of the Anus.—In the *Centralblatt für Gynäkologie* for May 4th there is an abstract of an article on the use of ichthyol in anal and other fissures, by Dr. Van der Willigen, published in the *Nederl. Tijdschr. v. Geneeskunde*. The author reports four cases of fissure of the anus in which healing took place speedily under the application of pure ichthyol. The drug was applied every morning and evening, also after each defecation, by means of a pencil introduced into the

The License to Practise in the State of New York.—Dr. Maurice J. Lewis, the secretary of the State Board of Medical Examiners representing the Medical Society of the State of New York, has sent us the following, dated May 23d: So many requests for information relating to the medical laws of the State are being received that it has been thought proper to call the attention of the profession to a feature of the existing law which expires by limitation on the 1st of August, 1895. Par. 148, ch. 661, of the laws of 1895 provides that persons "who matriculated in a New York medical school before June 5, 1890, and who received the degree of M. D. from a registered medical school before August 1, 1895, may without further examination, on payment of $10 to the regents and submitting such evidence as they may require, receive from them an indorsement of their licenses or diplomas conferring all rights and privileges of a regents' license issued after examination." From this it will be seen that after August 1, 1895, whether or not matriculated previously to June 5, 1890, all persons desiring to practise in this State must pass the medical licensing examinations. It will therefore be well for all entitled to the privilege of this exemption to file their applications for indorsement with the regents as soon as possible.

The legislature of 1895 has restored the penalty feature of the law as it stood previous to revision by the statutory revision committee, and medical malefactors and others unlicensed and unregistered may once more be prosecuted in the criminal courts. A vigorous enforcement of the laws by county medical societies is urged in hope of the benefit to be derived by the public as well as for the good name of the profession of medicine. The legislature of 1895 has also passed a law which will make it necessary for every person receiving the degree of M. D. from a medical college in the State of New York, after the year 1900, to have had an academic education equivalent to that required for graduation from a first-class high school or academy.

The Ontario Medical Association.—The fifteenth annual meeting will be held in Toronto on June 4th and 5th, under the presidency of Dr. R. W. Bruce Smith, of Hamilton. The programme includes the following papers:

The President's Address, by Dr. R. W. Bruce Smith, of Hamilton; Intestinal Complications in Gynaecologic Surgery, by Dr. J. B. Murphy, of Chicago; Embryonic Remains in Cases of Eczema of the Navel, by Dr. Robert T. Morris, of New York; The Operative Treatment for Bronchocle, by Dr. Francis J. Shepherd, of Montreal; Laryngeal and Tracheal Tuberculosis—The Importance of their Early Recognition and Treatment, by Dr. E. W. Chappell, of New York; A Discussion on Diphtheria, by Dr. W. J. Wilson, of Richmond Hill, Dr. G. M. Aylsworth, of Collingwood, and Dr. J. T. Fotheringham, of Toronto; A Discussion on Delayed Union in Fractures, by Dr. George A. Peters, of Toronto, Dr. J. H. Cameron, of Toronto, and Dr. A. McKinnon, of Guelph; A Discussion on the Physiological and Therapeutic Action of Iron, with a discussion of its Newer Pharmaceutical Compounds, by Dr. H. A. McCullom, of London, Dr. J. H. Sangster, of Port Perry, and Dr. A. T. Rice, of Woodstock; A Discussion on the Primary Repair of Genital Lesions of Childbirth, by Dr. K. N. Fenwick, of Kingston, Dr. H. Meck, of London, and Dr. H. T. Machell, of Toronto; The Present Position of Antitoxin in the Treatment of Diphtheria, by Dr. Charles Sheard, of Toronto; Antitoxin in the Treatment of Diphtheria, with Clinical Notes of Cases, by Dr. J. D. Edgar, of Hamilton; Colonel Fumigation in the Treatment of
MISCELLANY.

Diphtheria, by Dr. T. F. McMahon, of Toronto; Phlegmasia Dolens—Report of Cases, by Dr. J. Campbell, of Seaforth; Constipation, by Dr. H. Arnott, of London: The Treatment of Pulmonary Tuberculosis, by Dr. D. Marr, of Ridgeway; A few Remarks on Home and Foreign Climate in Consumption, by Dr. E. Playter, of Ottawa; Science in Medicine, by Dr. F. Oakley, of Toronto; Hydrotherapy in the Treatment of Exanthematous FEVERS, by Dr. A. K. Sturgeon, of Petrolia; Inflammations of the Optic Nerve—their Causes and Prognosis, by Dr. G. S. Ryerson, of Toronto; Cataret, by Dr. R. A. Reeve, of Toronto: A Case of Pneumoperitoneum, by Dr. C. J. Hastings, of Toronto; Puerperal Insanity, by Dr. X. H. Boomer, of Mimico; Narcotic Addiction, by Dr. D. Lett, of Guelph; Notes on Paralysis, by Dr. Ezra H. Stafford, of Toronto; The Use of the Stomach Tube, by Dr. G. Hodge, of London; A Case of Scurvy in a Child, by Dr. H. T. Machell, of Toronto; A Case of Progressive Unilateral Facial Atyrophy, by Dr. T. F. McMahon, of Toronto; A Case of Morphea, by Dr. A. McPhedran, of Toronto; Notes on an Epidemic of Hepatic Amygdalitis, by Dr. J. R. Hamilton, of Port Dover: The Antiseptic and Eliminating Treatment in Typhoid Fever, by Dr. W. B. Thistle, of Toronto; Traumatic Hysteria, by Dr. D. C. Meyers, of Toronto; Currents and Countercurrents in Therapeutics—A Plea for Rationalism in the Treatment of Disease, by Dr. H. H. Sangster, of Port Perry; The Intelligent Use of Rectal Injections with an Improvement of the Ordinary Enema Syringe, by Dr. P. P. Burrows, of Lindsay; Some Remarks on Pneumonia, with the Report of an Interesting Case, by Dr. R. V. Bray, of Chatham; Metallic Sutures in Fracture of the Patella, by Dr. J. J. Cassidy, of Toronto; Cases of Postpharyngeal Abscess, Double Cephalhematoma, Leucoma, Collitis, etc., by Dr. G. Acheson, of Galt; Traumatic Septicemia, by Dr. J. C. Mitchell, of Enniskillen; An Operative Procedure for Spina Bidta, by Dr. H. Howitt, of Guelph; Intestinal Anastomosis with Murphy's Button, by Dr. J. L. Dawson and Dr. L. Teskey, of Toronto: A Case of Anterior Abdominal Nephrectomy for Calculus, by Dr. L. MacFarlane, of Toronto; An Operation for Harelip, by Dr. A. Groves, of Fergus; A Case of Ectopic Gestation of Four Months and a Half; Operation and Recovery—A Case of Mental Ablerration following the Removal of an Ovarian Cyst, by Dr. W. J. Gibson, of Belleville; Tumors of the Bladder—Report of Cases, by Dr. F. LeM. Grasett, of Toronto; Seminal Vesiculitis, by Dr. E. E. King, of Toronto; Foreign Bodies in the Knee Joint, by Dr. G. Bingham, of Toronto; Modern Experimental Surgery on Man and Woman: A Criticism of Operations done and the Results obtained, by Dr. J. F. W. Ross, of Toronto; The Use of Isothal in Gynecology, by Dr. L. Sweetman, of Toronto; The Use of the Projection Microscope in the Teaching of Anatomy, by Dr. A. Primrose, of Toronto; A Display of Bacteria, by Dr. J. Caven and Dr. E. N. Starr, of Toronto: and Notes on Carcinoma, by Dr. H. B. Anderson, of Toronto.

An Unusual Case of Thyroid Disease.—In the Lancet for May 18th Dr. J. Hilton Thompson relates the following case, which, he says, is one of considerable interest owing to recent observations concerning the functions of the thyroid gland: A young man, aged nineteen years, came to the author some time ago with the following family history: The father was nervous and criminal; the mother also was neurotic. His friends stated that his manner had been peculiar, but could not say in what respect. The patient complained of a feeling of fullness in the head and what he termed "funny feelings," followed by depression of spirits. Dr. Thompson noticed that the neckband of his shirt was unbuttoned; on drawing his attention to it he said that it was too small for his neck. The author then examined his throat, and found the thyroid gland considerably and uniformly enlarged. The patient's face was slightly flushed and the pupils somewhat dilated. He was perfectly rational in his conversation. Potassium bromide in combination with liquor arsenicalis was prescribed. In a week the patient was in his usual health, and the thyroid gland had returned to its ordinary size. Three months after the author was called to see this patient again. He found him in bed in a state of intense excitement, and considerable difficulty was experienced in keeping him from hurting himself. When spoken to he answered rationally, but apparently with great effort. Every now and then he would have exacerbations of excitement, throwing himself about on the bed and punching his own head, or trying to dash his head against the bed-post. When he recovered from one of these attacks he usually appeared to be very hungry, generally demanding hot buttered toast. The thyroid gland was much larger than during the first attack; the shirtband would not button by an inch and a half. The face was usually flushed, but after the exacerbations became pale. There was no exophthalmia. There was no trouble with the excretions. Drugs had no effect. At the end of ten days Dr. Thompson had him removed to the workhouse hospital. While there he had two attacks. When he returned home he appeared to be in his ordinary health. The thyroid gland had shrunk to its normal proportions. During the following six months this patient had two "slight attacks" similar to the first described, and in each the thyroid gland was distinctly enlarged. The author says he has never previously seen or read of a case of this description. The temporary enlargement of the thyroid gland is the most peculiar feature. It appears probable, he says, that the increased size of the gland was the result of increased physiological action, the nervous symptoms that were such a prominent feature of the case being the result of poisoning by the large and unusual quantities of thyroid secretion thrown into the circulation.

The Use and Abuse of Antipyretics.—At a recent meeting of the West London Medical-chirurgical Society, a report of which appears in the Lancet for May 11th, Dr. William Hunter read a paper in which he pointed out that the extent to which antipyretic agents were used and their manner of employment were greatly influenced by our views of fever. After considering the analytic properties of the more recently introduced antipyretics derived from coal-tar products, such as antipyrine, phenacetine, and acetanilide, he said that the control of the nervous system was one of the principal points in the treatment of fever. The proper object of using such drugs was not to abolish fever by a summary process, but rather to bring the febrile process within reasonable limits. The administration of these remedies, he said, should always be cautious, more particularly in the case of acetanilide, the usual dose of which, as given in books (from three to ten grains), was much too large; it should be from one to three grains.

Dr. Banning remarked that no antipyretic equaled the use of cold sponging and cat vials, either in efficiency or in safety. Dr. Eccles believed that the direct action of antipyryne could be attributed to its reducing qualities, removing oxygen from the protoplasm of the nerve cells, and thus diminishing activity and producing analgesia. Dr. Atkinson said that he had not found any benefit follow the use of antipyretics, and thought that, as the temperature always fell before death, high temperature by itself would not kill a patient. Mr. MeAdam Eccles referred to surgical cases where high temperature was due to nerve influence, especially in cases of head injury followed by high fever without sepsis, and to the so-called catherer fever. He said that after injuries of the head the temperature was often different on the two sides.

DERMATOLOGICAL NOTES
FROM THE KINGS COUNTY HOSPITAL.

By HENRY H. MORTON, M.D.,
ATTENDING SURGEON,
DEPARTMENT OF CUTANEOUS AND GENITO-URINARY DISEASES,
KINGS COUNTY HOSPITAL AND LONG ISLAND COLLEGE HOSPITAL Dispensary;
ASSISTANT TO CHAIR OF GENITO-URINARY DISEASES,
LONG ISLAND COLLEGE HOSPITAL;
EXPERT IN CONTAMINOUS DISEASES, BROOKLYN HEALTH DEPARTMENT.

Dermatitis Exfoliativa Neonatorum.—In 1878 Professor von Rittershain described* a disease of the newly born, which had never been previously reported and which occurred for the first time in his large experience, extending over a number of years, in connection with the Findel Anstalt in Prague, in this institution in 1868. In the succeeding ten years two hundred and ninety-seven cases occurred, of which one hundred and forty-five terminated fatally. The children were generally attacked in the second week, sometimes in the fifth week, but seldom later.

The prodromal stage consisted in a mere increase of the normal epidermal exfoliation, which gave place to the erythematous stage. A redness would begin upon the face and facial mucous membrane which rapidly extended over the entire body. The stage of exfoliation soon followed; the epidermis became thickened and raised up off the cutis. Friction over the surface tore off the scales in large flakes, and on the hands and feet the epidermis could be pulled off like a glove.

The exposed cutis became covered with dried secretions forming crusts. Death resulted from general exhaustion, lung complications, or intestinal catarrh.

Von Rittershain expressed himself as very much in doubt as to the etiology of the disease, but assigned as a possible cause, septic infection through the buccal mucous membrane.

Caspar*† considers the disease to be an epidermolyis of unknown nature, with secondary hyperemia of the cutis, and regards it as an acute disturbance occurring in the external layers of the skin which do not contain blood-vessels.

G. T. Elliott states that Riehl has found a fungus with long, thin mycelia, † and concludes this to be the cause of the disease.

During my service at the Kings County Hospital I met with, for the first time, a case similar to those described by von Rittershain.

The mother was a healthy young Irish woman, twenty-two years of age, who was delivered of her first child in the hospital. The labor was normal in character and the child weighed eight pounds. Seven weeks after the child's birth it was transferred to the dermatological wards on account of an eruption on its skin, with a history of having been perfectly well for the first four weeks. The eruption began on the face and in two days the entire body was bright red. In about a week the epidermis began to chip and scale off and continued to scale for three weeks. The desquamation lasted a few days and when the entire epidermis had desquamated the body remained smooth and red for a few days, and then desquamated again, beginning first as a mere cracking of the epidermis, with a subsequent peeling. The epidermis has been exfoliated at three different times. At the end of three weeks the face was looking clean and the head was covered with a dry crust. The nails were not affected, and the palms and soles were free at all times. The child was well nourished in appearance and not notably restless.

The treatment which was employed was linseed oil externally applied on cloths kept in contact with the skin continually and frequently renewed, and Fowler's solution in drop doses three times a day internally.

After the treatment was begun the child did not desquamate again, the redness and congestion of the skin gradually subsided, and the child went out well.

I believe, however, that the process was practically at an end before the treatment was instituted, and the cure was due to the inherent tendency of the disease to recovery in a vigorous child.

An Eruption resembling Pityriasis Maculata et Circinata probably induced by Alcohol.—The patient, aged twenty-eight years, and a domestic by occupation, drank heavily for two weeks prior to the appearance of the eruption, which occurred first as one spot on the face and then showed itself over the entire body in twenty-four hours. (Fig. 1.)

The patient states that it was bright red in color when it first appeared, but has become darker since then. It had lasted for one week, and now presents the following appearances:

Description.—The eruption is located on the face, neck, trunk, arms, thighs, and legs. It consists of circular spots, not elevated above the skin, of a dark-red or brick color, ranging in size from a three-cent piece to an inch in diameter, with well-defined borders. Some of the larger spots seemed to be formed by the coalescence of two or more smaller ones. On the abdomen the macules are larger in size and not so sharply defined at the periphery. There is no tendency toward a clearing up in the center. Slight pressure produces disappearance of the spots on the body, but on the legs they do not entirely disappear on pressure, a slight degree of pigment remaining behind. There has been no itching of the eruption at any time. A certain amount of desquamation is taking place which is not branny in character, but consists in a loosening en masse of the entire epidermis covering each macule. When this first begins it gives rise to a glazed appearance over each macule, and on pinching up the skin very small fine wrinkles are formed; as the desquamative process goes on the central portion of the loosened epidermis is thrown off in many of the spots, leaving a ring of loosened epidermis attached all round to the peripheral margin of the macule.

The patient admits having had cuts three months ago, but not since then, and denies having had any sores on the vulva or other signs of syphilis; examination shows no evidence of a chancre or unaceous patches. Lymphatic glands are not enlarged, with the exception of some in the groin.

The patient was kept under observation without any treatment excepting a simple placebo internally, and in the course of about ten days the spots finished desquamating, the con-
gestion subsided, and she was discharged as cured from the hospital.

Pityriasis maculata et circinata, as it is called in the classification of the American Dermatological Association, or pityriasis rosen, as its original describer, Gibert, named it, is one of the rarer skin diseases, having occurred only 278 times out of 205,000 cases of skin diseases, represent-

but identical in appearance with the organisms found in other desquamating non-contagious diseases.

Others, again, consider it as a reflex result of the uric-acid diathesis or of digestive disturbances.

Kaposi * denies its separate existence, and believes it to be the same as herpes tonsurans maculosus, or ringworm of the body, which he proves by finding the trichophyton constantly present and having a direct relation in its life and growth to the duration of the disease, and also by the experimental and accidental inoculation of other patients with the spores, with the result of producing the disease in them.

In the case I have reported above I examined the scales microscopically, but did not find any fungl or spores, and I should be inclined to consider the outbreak in this case as directly due to the ingestion of large amounts of alcohol and its irritating effect upon the vaso-motor centers supplying the cutaneous arterioles.

The chief interest in pityriasis maculata, however, lies in the extreme similarity of its appearance to other diseases of the skin, notably the macular or erythematous syphilide, and, since so many unpleasant situations may arise from mistaking an innocent and non-contagious skin eruption for a communicable and generally considered disreputable disease, it is always well to bear this affection in mind before making a positive diagnosis of syphilis in every questionable case, although the lighter tint, branny scaling, and absence of mucous patches and glandular enlargements will generally serve to exclude the latter disease.

Eczema Marginatum.—Eczema marginatum, as it was named by Hebra, who first described it, or tinea trichophytina cruris, or ringworm of the crotch, as it is sometimes called, is the result of the local inoculation of the trichophyton fungus, and the peculiarities of its growth and distribution are favored by the local conditions of the parts upon which the organisms become ingrafted. It is not an uncommon disease in adults in this country, and occasions great discomfort from the severity of the itching, which at times, particularly at night, is most intense. The scratch-

*Journal of Cutaneous and Genito-urinary Diseases, December, 1893.

* Pathologie und Therapie der Hautkrankheiten, p. 916.
ing by which the patient attempts to relieve himself tears off the upper layers of epidermis and numerous bleeding excoriations are the result. It is very obstinate in yielding to treatment, and after it is apparently cured a relapse often takes place, for the reason that a few of the fungi have been left to form a new local center of infection from which the disease rapidly spreads again. In the tropics it is not only more frequent, but from the constant sweating macerating the skin a fertile field for the luxuriant growth of the parasite is afforded, and it reaches an extent to which we seldom see it here. Under these conditions it is spoken of under the name of "Burmese ringworm" and "Chinese ringworm." *

In this climate the eruption is usually limited to the inner side of the thighs, the perineum, anal folds, and serotum, but it may extend on to the abdomen and buttocks. It begins as a small, round, red, inflammatory patch, which rapidly spreads, often having a tendency to heal in the center and leaving a mere brownish pigmentation to indicate its former site. But its particularly marked feature is the abrupt ridge which bounds it on all sides, even when the skin within is nearly normal in appearance.

It is this elevation of the margin of the patch, and the sharp line of demarcation between it and the healthy skin without, that earned for it the name of eczema marginatum, and is the important point upon which the diagnosis from ocular inspection is made. This diagnosis can be readily verified by examining some of the epidermal scales soaked in dilute liquor potassae under a moderately high-power objective, which shows numberless round black dots in and upon the epithelial cells, sometimes arranged in clusters and sometimes separate, and often accompanied by threads or mycelia.

In the case reported below, the child had been in the children's ward at Kings County Hospital, where many of the children had ringworm of the head and body.

The peculiarities of the case are the extent and distribution of the eruption, the fact that it produced but little discomfort, and the readiness with which it yielded to treatment—all of which features can be accounted for by considering the thin delicate character of an infant's skin.

* I am informed by a patient who spent some time in Cuba that the natives are in the habit, after they have taken long rides on horseback, of washing the seat and inner margin of the thighs with brandy, probably with a view to prophylaxis against infection with the trichophyton.

J. S., aged six months, mother healthy and free from syphilis. The child was nursed, its digestion was in good order, and it was well nourished in appearance. The eruption appeared four or five weeks before I saw it first, beginning around the vulva and gradually increased in extent, spreading continuously at the margin. At this time it was located around the vulva and anus and on the inner side of the thighs, extending on to the abdomen and on the buttocks. The eruption was smooth, bright red, not elevated above the surface, and with but little scaling except at the margin of the patch, which was slightly elevated. There was a very abrupt line of demarcation between the healthy and the diseased skin. There was neither ulceration nor weeping, and the skin inside the boundaries of the line of demarcation was smooth and healthy, and except for the congestion would have been normal in appearance.

The umbilicus was similarly affected. There were two spots on the abdomen and three on the back, of about the size of a cent, dry, bright red, sharply defined, and covered with adherent scales. A microscopic examination of scales scraped off showed large numbers of round spores in and upon the cells.

A two-per-cent. resorcin ointment was ordered to be rubbed thoroughly into the spots, and in the course of six weeks the lesions disappeared completely and the skin was left smooth and natural in color and texture.

40 Schermerhorn Street.

Experimental Anatomical Investigations into the Influence of Tuberculocidin and Tuberculocidin upon Inoculation; Tuberculosis in Rabbits' Eyes.—Buns (Arch. fär Ophthal., xxxix, 4) draws the following conclusions from his investigations:

1. Neither tuberculocidin nor tuberculocidin can prevent or put a stop to the process of inoculation-tuberculosis once started in a rabbit's eye, much less cure it.

2. There is no essential difference in the course of the tuberculous process under tuberculocidin or tuberculocidin.

3. The tuberele bacilli seemed to be met with in greater numbers in the animals inoculated than in the control animals.
AN ELECTRIC PRESSURE SOUND FOR THE DIRECT VIBRATION OF THE MEMBRANA TYMPANI.*

By JOHN C. LESTER, A.M., M. D.,

ASSISTANT TO THE CHAIR OF OTOLARYNGOLOGY, BELLEVUE HOSPITAL, MEDICAL COLLEGE; ASSISTANT SURGEON TO THE ST. BARTHOLOMEW'S CLINIC FOR THE EYE, EAR, THROAT, AND NOSE; EX-EDITOR, AMERICAN MEDICAL DIGEST; FELLOW OF THE AMERICAN ACADEMY OF MEDICINE; MEMBER OF THE MEDICAL SOCIETY OF THE COUNTY OF KINGS.

The value of vibratory massage in the treatment of diseases, especially the atrophic, of the upper air-passages, has been fully attested by many careful observers of recent date. Dr. Michael Braun,† of Triest, in a paper read before the International Medical Congress at Berlin, was the first to call attention to the value of massage in diseases of the nasopharynx.

Dr. Carl Laker‡ has also written an exhaustive monograph on the same subject, in which he enthusiastically indorses this method of treatment. To Dr. W. Freudenthal,* of New York city, perhaps more than to any other, is due the honor of having devised an electrical instrument for massage in diseases of the nose and throat. More recently Dr. G. Melville Black,§ of Denver, calls attention to the value of lateral vibratory massage in diseases of the nasal mucous membrane. Possibly the inspiration of all these writers on the value of massage in naso-pharyngeal diseases was received from an investigator no less distinguished in another field—Dr. August Lucæ.¶ In an article on A New Method for the Mechanical Treatment of Chronic Diseases of Motion in the Conducting Apparatus of the Acoustic Organ, Lucæ first described an instrument for direct mechanical vibration of the membrana tympani. Lucæ's device consisted essentially of a steel sound carrying at its end a hollow cone, which is controlled by a handle composed of a small tube and an adjustable spiral spring. The cup-shaped extremity of the sound is applied to the short process of the malleus, and, being manipulated by the hand of the operator, must necessarily be limited as to degree, extent, and number of impulses.

The fact that so simple and crude a mechanical device has led to marked therapeutical results in certain forms of middle-ear disease, as has been certified to by its author and other eminent aurists, sufficiently exceses the writer for presenting the following illustrations and description of an instrument which has proved more than satisfactory in those cases of impaired hearing and tinnitus which are directly traceable to some defect in the conducting apparatus of the ear.

In the first illustration (Fig. 1) the instrument is shown in position. As will be seen, the head of the patient is turned slightly toward the opposite side as for an ordinary examination of the middle ear, and firmly fixed in this position. An ordinary round ear speculum is introduced, and the canal illuminated in the usual manner. The speculum is omitted from the illustration in order to show more clearly the position of the sound as it enters the external auditory canal. The motor with pressure sound attached is shown in Fig. 2. The right hand grasps the handle of motor, with the thumb resting on the button of the contact spring. The corrugated handle B (Fig. 3) of the pressure sound A (Fig. 3) is firmly held between the thumb and index finger of the left hand. The tip of the little finger is made to rest gently on the head of the patient immediately behind the auricle, and the sound is introduced parallel to the anterior superior wall of the auditory canal, until the cylindrical extremity of the spiral end D (Fig. 3) rests upon the base of the short process of the malleus. The short process of the malleus is selected as the point of contact, as it has been demonstrated by Lucæ* that "if the malleus is still movable, more or less free movements are seen at once to take place in the whole drum membrane, which in the majority of cases correspond to the movements of the short process—i.e., occurring inward on pressure upon the latter, and outward on removal of pressure." Dr. E. B. Dench,‡ in his recent work on the ear, referring to the same subject says: "It has been demonstrated that pressure exerted at the short process of the malleus is communicated directly through the incus to the foot plate of the stapes, and from this to the labyrinth."

---

* A rough model of this instrument, which the writer intended to have had presented to the Section in Otology of the American Medical Association, at Washington, in 1894, arrived too late for such presentation.

‡ Dench. Diseases of the Ear, p. 382.
When contact is made with the pressure button before referred to, vibrations ranging from five hundred to fifteen hundred or more a minute, judging from the note obtained from the revolutions of the armature, are produced. The extent or length of the vibrations is thoroughly controlled by the eccentric throw G (Fig. 3) and the binding screw H (Fig. 3), the range being from zero to half an inch.

In the cases so far treated the best results have been obtained by a minimum length or extent of vibrations and a maximum number of vibrations. It is seldom that the binding screw has been further removed from the center of the eccentric throw than a sixteenth of an inch, and when this minimum length of stroke has been adhered to, in no case has the patient experienced pain.

In a few instances, where a slight discomfort has been noticed, examination has shown this to be due to undue pressure on the speculum. Eczematous and excoriated canals, of course, must be cured before beginning the massage of the drum membrane.

The duration of treatment varies, the average being from three to ten seconds at each sitting, and should be repeated from two to three times a week.

A few mechanical hints, developed from several months' use of this instrument, may not be unwise at this point before presenting a few histories illustrating its therapeutic value.

The motor and sound should be firmly and steadily held in the same plane (see Fig. 1). As the motor and sound are carefully adjusted to run smoothly at right angles, any twisting of the motor will cause an immediate binding of the shaft E (Fig. 3). The pressure sound A (Fig. 3) is made an inch longer than the handle B (Fig. 3), to allow for the length of vibration, and the handle must be held in the center of the sound.

The cylindrical end of the sound A (Fig. 3) enlarges toward its distal extremity and in shape resembles more nearly a truncated cone. It is hollowed out, as will be seen by the dotted lines in the cut, not only to better adapt itself to the short process of the malleus, but also to receive a pledget of absorbent cotton or other soft material in order to prevent any possibility of mechanical injury. Sounds with spirals of different strengths have been found necessary, and in every case the writer has found it wiser to begin with the one of least resistance, and to continue its use until the patient's confidence has been secured and a certain degree of tolerance obtained. The motor is adapted to a two-volt current. Any good storage cell will suffice.

A few brief histories are presented to show the results obtained. In each case reported other methods of treatment had been persistently tried without lasting, and I might say with no benefit.

Case I.—Essie L., aged nineteen years; occupation, dressmaker. Came to St. Bartholomew's clinic for treatment on December 4, 1894. Complained of deafness and constant ringing in both ears. The following history was obtained: Deafness and tinnitus in both ears for three years; unable to state in which ear symptoms began first; has had treatment for nine months, with the result of a slight improvement in hearing, but no relief from the tinnitus; never had pain or discharge from either ear; no assignable cause; no heredity.

Examination.—Auricles and canal normal; both membrane tympani uniformly cloudy and moderately retracted, but not funnel-shaped; light reflex lost; short process not unduly prominent; little or no fibrous tissue; membrane moved throughout by Siegle's otoscope; handle of malleus slightly foreshortened; Eustachian tubes patent; watch heard on contact only; bone conduction markedly increased; lower tone limit elevated; chronic catarhal inflammation of the nasopharynx.

This case will be readily recognized as one of chronic catarrhal otitis media.

Treatment consisted of ordinary cleansing and care of nasopharynx and direct massage of the ossicular chain three times a week, each treatment lasting from five to thirty seconds, or until there was marked congestion of the vessels about the long.
process of the malleus. The ready congestion of the tissues immediately around the handle of the malleus, the writer believes, has much to do with the prognosis in a given case. After the third massage, the tinnitus, which had been greatly diminished in intensity by the previous treatments, ceased, and the hearing distance increased to an inch.

January 14, 1895, date of last visit, hearing distance had increased to four inches ($\phi$) and tinnitus had returned.

Case II.—Allied to Case I, but of longer duration, is that of C. F. M., aged forty years; occupation, physician. Eight car chiefly involved; tinnitus and impaired hearing for five or more years; no pain; no discharge; no hereditary tendency. Aural case was found to be normal; slight squamous exudate seen on canal; drum membrane dull; no light reflex; scar tissue marked; movement of drum and malleus limited; short process prominent and long process foreshortened; ossicles firmly bound together and mucous membrane apparently thickened; Eustachian tube open, but not freely so; slight mucous rhonchi; watch heard on close contact; chronic hypertrophic nasopharyngitis and pharyngeal tonsils filled with leptomithrix masses.

Treatment begun March, 1894. Polioltization; use of Delstanche mass; applications to the nasopharynx and squeezing out of the masses from the tonsils resulted in a decided improvement of the general condition, but no corresponding improvement in the symptoms most complained of.

Treatment was discontinued during the summer to be resumed early in December; conditions the same as before treatment, with the exception of the nasopharynx. Direct massage was immediately begun on patient's return, and treatment of nasopharynx continued. The lessening of the tinnitus began with the first massage, and at present writing, March, 1895, hearing distance for affected ear is two inches ($\phi$) and tinnitus can only be heard occasionally at night with the head resting on a pillow.

Case III.—A. M., aged twenty-nine years, began treatment February 4, 1895.

Complained of loss of hearing and tinnitus in both ears, more pronounced in right ear; duration, four years; has had an occasional furunculosis of both canals. Examination revealed a case of chronic catarrh of the middle ear. Watch heard on contact, A. D., and at an inch ($\phi$), A. S.

Patient has had massage of drum membrane twice a week regularly.

On March 14th, date of last record, watch was heard by A. S. at seven inches ($\phi$), A. D. two inches ($\phi$). Entirely free from tinnitus.

From the cases herewith reported, and from a large number now under treatment, both in private practice and at the clinic, the writer feels justified in the following conclusions:

That in the mechanical mobilization of the ossicles by vibratory massage we have an agent of undoubted value in chronic and subacute affections of the middle ear. That the therapeutic value of this method depends largely on the rapidity and amplitude of the vibrations.

That it is a safe method of treatment in all cases of impaired function due to some defect in the conducting apparatus. That it is of especial value in sclerosis and in atrophic conditions by virtue of its action in increasing the vascularity and hence the nutrition of the part.

That in hypertrophic otitis media this method is safer and to be preferred to the pneumatic method of Delstanche, which is unsafe and in many cases positively harmful.

That it is a method easy of application, causes little or no reaction, and is unattended with pain or discomfort to the patient.

Since writing the above, we have been especially fortunate in having obtained and read an article by so eminent an authority as Dr. P. Garnault,* who has devised and used an electric pressure sound similar in construction to the one described above.

In addition to massage through the external auditory canal, Dr. Garnault has employed rapid (six hundred to seven hundred per minute) vibrations through the Eustachian tube to the drum membrane, which he believes to be especially useful in certain labyrinthine diseases.

Garnault's results have been corroborative of those published by Lucas.

The value of rapid and mechanically accurate vibrations particularly emphasized by this writer.

A CASE OF SKULL DEFORMITY FROM INHERITED SYPHILIS.†

By CHARLES E. NAMMACK, M. D., ATTENDING PHYSICIAN, NEW YORK HOSPITAL, OUT-PATIENT DEPARTMENT.

Ericsson W. D., a negro boy three years and a half old, was brought to the dispensary, April 14, 1895, on account of a peculiar deformity of the skull. The mother states that at his birth the womb was very slow to open, and the attending physician inserted a rubber bag to facilitate dilatation. The bag and child were expelled together. On washing the child for the first time, about the fourth day, she had noticed a swelling in the region of the anterior fontanelle, but had been assured that it would gradually disappear. Instead of doing so it has remained and grown harder. The child is bright, lively, and good-tempered.

Examination shows an exostosis of the frontal bone, thickest at its superior angle of junction with the parietal bones, and extending downward with diminishing thickness over the external surface of the vertical portion of the frontal bone. Pressure on the growth produces no symptoms. The child's eyes are large and the eyeballs prominent. The diagnosis is between cephalhematoma which has undergone ossification and hereditary syphilitic bony hypertrophy. It will be remembered that in cephalhematoma the pericranium is elevated by extravasated blood, but does not lose its vitality, and begins to secrete from its under surface preparatory to the formation of bone. As the blood becomes absorbed, the cavity at length becomes obliterated, and there remains some thickening of that part of the cranium which corresponds with the site of the tumor (J. Lewis Smith, seventh edition, p. 117). The writer has seen this classical course followed in several cephalhematomata, but never the amount of thickening left which exists in the present case.

In favor of hereditary syphilis, the mother's previous history offers some points. Her first pregnancy terminated at term in the birth of a dead child. Hemorrhage preceded the birth, forceps were applied, and the dead child extracted. Her second pregnancy resulted in abortion at the second month. Our

† Patient presented at meeting of Section in Pediatrics, New York Academy of Medicine, May 9, 1895.
The case differs from cases of rachitis in the following particulars: 1. The skull bone is thickened by new growth, rather than expanded and thinned, as in rachitic craniotabes. 2. The shafts of the long bones are affected rather than the epiphyseal ends. 3. The crests of the tibiae are enlarged and broadened, instead of being thinner than normal, as is usual in rachitis. 4. There is no cachexia present. 5. Ordinary symptoms of rachitis, such as prominent abdomen, beaded ribs, pseudo-paraplegia, and attacks of laryngismus stridulus, are absent. The tibial changes are well shown in the accompanying illustration.

No. 29 East Twenty-fourth Street.

SPECIALISM IN MEDICINE.*

By W. K. SIMPSON, M. D.,
FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

The subject of the division of the practice of medicine into its various specialties is one that has claimed the attention of the profession for many years, having its long list of advocates and antagonists on either side, and it will, in all probability, remain a matter of argument for many years to come; but never before has the subject been so ripe as at the present time, and never before has the profession been so unanimous toward the solution of the problem. As science and civilization advance, the matter of simplification becomes an all-important consideration, and we naturally see it creeping into every branch of human thought and labor, marking, as it were, the first great step toward true progress and advancement. Naturally, the first great law of simplification is a proper division into component parts, whereby minor details receive their due attention and a permanent structure is at last perfected.

Before entering upon the subject as it concerns our own, let us see how the principle applies to some of our kindred professions. Take that of the law, for example, and at the outset we meet with the two great divisions into criminal and civil practice, the latter being still further subdivided into numerous branches—for instance, patent, real estate, and railroad—each more or less separate from the other and requiring a different train of thought in its pursuit, but still all being dependent on the same fundamental laws of reasoning. Again, here is still even a higher division into the various courts—over and under, supreme, superior, common pleas, surrogate's, and the appellate court—each disposing of cases that come under its own especial jurisdiction. Perhaps there is no other profession where the line is so accurately drawn as in the law, and we can see at once what a simplifying effect these divisions possess, for without them litigation would be much more chaotic both for lawyers and clients.

This same principle applies (though possibly not in so strict a sense) to the profession of engineering, the chief divisions being the civil, mining, and mechanical, there being the same underlying principles in each, though the practical application may differ very widely one from the other.

Turning our attention to mercantile pursuits of any magnitude, we see this same law of division enacted.

* Read before the Hospital Graduates' Club, January, 1895.
In manufacture, we see artisans spending their whole life of toil on some one special portion of work, being ignorant, perhaps, of the other branches.

The various departments of the government, national and otherwise, show to a marked degree the efficacy and necessity of this same division. The minuteness of the postal service, for instance, is a most striking example.

In the domain of art we notice the same principle. The artist and sculptor gain their reputation by confining their abilities to one special fancy. The perfect portrait painter and landscape painter are seldom combined in the one person; the beautiful marines and interiors are by different artists, and this concentration of ability is so often marked that it is often a matter of ease to detect at a glance the individuality of certain artists.

In this instance the division into special work is, perhaps, more of a natural division, being a cultivation of a peculiar fitness or bent of mind. Still, it shows the point we are after, that perfection is more readily gained by pursuing one definite line of action.

The pursuit of the sciences in their varied and vast domain is another instance of the value of special research. We have the astronomer, naturalist, chemist, physiologist, each in his own sphere, affording a grand opportunity for a life's devotion.

Education, in its numerous phases, shows the necessity for special training and application. And so we could go on multiplying examples to infinity, showing that whatever calling we may pursue in which a certain degree of perfection is to be reached, a proper consideration of and devotion to its special branches is absolutely necessary.

Having thus seen, to a certain extent, the application to and necessity of specialism in other branches of human endeavor, the question naturally arises, Does it not apply with equal or if not more force to the medical profession?—a question easily asked, but possibly not so easily answered. When we come to compare our profession in this respect with other callings, we at once find many obstacles in the way which seemingly render such a comparison a matter of difficulty. Principal among these, and upon which all other objections more or less depend, is that the practice of medicine is not an exact science. We can not proceed with mathematical accuracy. There is no court of appeals, save the autopsy table—and how often that reveals the fallacy and error of previous theory! No set of laws govern all cases; there are personal idiosyncrasies; many phenomena of disease are shrouded in mystery. The same disease attacks different persons in different ways. Unforeseen complications are constantly arising; theory and speculation naturally form the basis of many of our conclusions, so that we often flounder in a sea of uncertainty. Again, we must remember that we are dealing with the manifold changes of the human body—a complex organism, not made up of component parts that admit of entire isolation, but rather a structure, the various portions of which, nourished by the same medium, must act in perfect harmony with each other for the proper maintenance of life, the overthrow of one organ or function generally carrying disaster to some other on which it may depend, or perhaps throwing the whole system into a state of disease and ultimately causing death. Our daily practice is full of such illustrations; sufficient for the purpose may be found in the relations which the circulatory and nervous systems bear to each other and to the whole economy—e.g., a piece of vegetation leaving the heart produces death by cerebral embolism; interference with return circulation produces distant edema; arrest of arterial circulation produces gangrene; reflex disturbances are so abundant that at times it is hard to know where to seek the source of trouble; and how much is included in that great term hysteria! A due consideration of these facts in all their bearings will present some of the difficulties to be encountered in reducing our profession to a system of exact specialties.

Seemingly strong, however, as these objections may at first appear, there is, no doubt, a very positive affirmative side of the question. Medicine, as a science pure and simple, naturally divides itself into specialties; but it is in their application to our daily practice that we as physicians have to consider them.

The rapid advances that have been made and are still being made in our profession have caused it to assume such gigantic proportions that one can not expect to be master of the whole science, and any attempt or boast to that effect meets with just ridicule by more modest men. We are all daily meeting with cases which, owing to our lack of special knowledge, the possession of proper apparatus, or the time and facilities for proper treatment, we are unable to justly care for, and there remains no other alternative than to seek the aid of some one who is better fitted to treat the case. The patient's welfare should claim our first attention, and no one knows better than the physician himself whether or not he is doing his duty to his patient. Far better for a practitioner to send a patient for additional advice of his own accord than to have a patient seek the specialist himself after a term of misguided treatment; the first creates a mutual holding of confidence between physician and patient, and I might add, in passing, that the reference of a patient to a specialist entails on the latter a trust of honor that can not be too strongly guarded. It is, perhaps, this breach of confidence that in some instances has brought odium on the practice of specialties.

It is often the experience of specialists to correct the errors and oversights of the general practitioner. The endeavor to do all we can for our patients is commendable, but to keep them out of the hands of specialists on the score of prejudice savors somewhat of deception. That one can arrive at a greater degree of perfection in the concentration of his medical knowledge than in trying to absorb the whole subject no one will deny; that reputations may be made quicker is also an equally undeniable fact. The chances for brilliant successes are much greater in specialties, and the wear and tear attending a physician's life is certainly lessened. The practice of medicine is fast losing its sentimentalism, and the public at large is becoming a potent factor in its influence on the profession—their demands can not be ignored. People of the present time, in many instances, determine themselves as to about what their ailments are, and look about them to find out
who is best fitted for their individual case, and naturally
go to a specialist. We can not deny them their right of
choice, and I am sure we can not stop them. This in a
measure regulates the supply and demand, and as long as
the laity clamor for specialists they are sure to exist.

The present drift of medical research tends to special-
ism; we see this strongly instanced in the division of so-
cieties, academies, and congresses into separate sections.

Medical journalism abounds in publications devoted to
special subjects. Health boards demand specialists. Mat-
ters requiring expert testimony surely call for specialists,
and the medical educator must needs be a specialist. In
return, it is needless to say that the specialist himself
should be a man of broad medical views and thorough
training in general medicine, for in the pursuit of no one
specialty can we lay aside the laws of differentiation and
the relation that one morbid action bears to another.
True specialization is a limitation of work rather than a li-
imitation of knowledge, and any one entering it without proper
preparation will soon find the limitations of his action.

Routinism is an objection raised against specialization,
but I think we find just as much of it in the humdrum
and weariness of general practice. The careful specialist is
ever on the alert for new ideas and methods, and there
yet remains to be found the specialty which has been mas-
tered.

The eagerness to bring all cases of disease under the
specialty in which the physician is interested is another
objection offered; this will only happen to the blind and
narrow enthusiast, who is a danger to be feared in any
sphere.

After having considered the evident present tendency
toward specialization, it might be well to consider the debt
that the profession owes it. The relief from former igno-
rance and chaos has been the result of men devoting
themselves to special work. The microscope and pathology are
brilliant examples. Special surgery has allowed the ex-
ploration of regions of the body with impunity which in
former times were closed to all knowledge, yielding results
which seem but little removed from the miraculous. Look
at it as we may, specialization is a natural culmination of the
advancements made in the science and practice of medi-
cine, and, as a result, gynecology, ophthalmology, neu-
rology, orthopaedics, laryngology, otology, dermatology,
and many others have reared domains of their own which
are far from being circumscribed; and it has not been the
work of narrow-minded men, but men of broad minds and
actions that have put specialization on a sure foundation and
doubtless have made it the practice of the future.

952 Lexington Avenue.

The Value of Diphtheria Antitoxine Serum.—At the re-
cent meeting of the American Pediatric Society, held at Hot
Springs, Va., it was resolved that in the opinion of the society
the evidence thus far produced regarding the effects of diph-
theria antitoxine serum justified its further and extensive trial.

The Louisville, Ky., Academy of Medicine.—At the last
meeting, held on Monday, the 3d inst., the subject for discus-
sion was The Milk Supply of Cities.

THE PROGNOSIS IN NASAL OPERATIONS
PERFORMED DURING
EPIDEMICS OF LA GRIPPE AND OF ALLIED CONDITIONS.*

By D. BRYSON DELAVAN, M. D.

The ultimate success of any surgical operation will depend,
as every one knows, upon the conditions of the patient, local and general, which existed at the time the operation was performed; thus, an organ which is in a state of violent inflammation would be allowed by the operator to assume a somewhat normal condition before he would attempt to interfere with it, unless the circumstances requiring operation were of decided urgency. The more highly organized the organ, the greater the activity of its circulation, the more intimate its association with other organs of an especially important character, the more abundant its lymphatic supply, and, finally, its comparative in-
accessibility, the greater would be the hesitancy in inter-
fering with it under adverse circumstances.

As trite as are these statements, it has seemed not
unfitting to the writer to call attention to certain aspects of
nasal surgery with which we are frequently confronted, and
which, it has seemed, have failed to receive due attention. Perhaps this matter has been brought to the notice of the
writer in great measure through the fact that cases have so
often been referred to him by other practitioners, with a
request that he would operate and at once, when he has
been conscious of the fact that, however safe in general the
proposed procedure might be, the special conditions obtain-
ing were such as, for the time being, to interdict surgery
altogether.

The views herewith expressed upon this subject have
been purchased at the expense of several involuntary but
costly experiments gained during epidemics of grippe which
have prevailed during the last few years, and the lessons
learned from them have been so clear and decisive that I do
not hesitate to communicate them. I am almost ready to
advance as a dictum the proposition that during epidemics of
grippe, surgically speaking, the nose should be let abso-
lutely alone. In the first place, it will be noticed that when
the grippe prevails, any operation upon the nose is apt to
be followed by an acute attack of influenza, and this in
spite of the fact that up to the time of the operation the
patient may have shown no signs of any such trouble.

Operations upon the nose of any considerable severity
are very sure to be followed by a certain amount of general
depression, and, while this is not invariably the case, it is
not too much to state that it is the rule.

Again, as the result of the operation, there is a neces-
sary amount of local irritation, and, finally, that possibly
complicating feature, an open wound. All of these things
directly tend to invite an attack of the grippe. The possi-
bilities of such an attack, moreover, are added to by the
fact that during such epidemics large numbers of persons
are affected, and a patient about to be operated upon may
have been already exposed and about to develop an attack
which, at the time of the operation, has not clearly mani-

* Read before the Hospital Graduates' Club, April 25, 1895.
fested itself. Whatever may have been the real cause of
the matter, and however blameless the surgeon in produc-
ing it, it is safe to say that, where such complications su-
prevene, few patients will have either the intelligence or
the common sense to refrain from accusing the physician of
having been directly responsible for their sufferings.

Secondly, the results of such an attack in a patient who
has suffered even the slightest injury to the nose through
operation are apt to be disastrous.

First, with regard to the present condition of the pa-
tient. The attack of influenza will probably induce a con-
dition of violent irritation in and about the injured parts.
Swelling is intense, so that not only is the wound undoubt-
edly congested, irritated, and compressed, but the secretions
are retained, drainage is interfered with, and the possibili-
ties of local treatment, so necessary in the after-care of such
cases, are practically abolished. With such difficulties to
contend with, it needs no argument to prove that recovery
will be greatly retarded, and a wound which, under ordi-
nary circumstances, should have healed in a comparatively
short time, will remain open, perhaps indefinitely. Length-
ened recovery in such cases is one of the most unfortunate
accidents that could occur, not only with regard to the com-
fort of the patient, but also in view of the ultimate success
of the operation, for, as is well known, the quicker the heal-
ing process, the less liability there is to the formation of
objectionable cicatricial tissue, adhesions, and other compi-
cating results; indeed, skill in operating would almost seem
of secondary importance to the proper after-care of the case.

As a rule, these nasal operations do not require urgent
haste. In most instances the patients have suffered from
nasal obstruction for a greater or less length of time, and
the conditions are such that a few weeks of waiting would
not be likely to involve any serious injury. It would be
better not to operate at all in some cases, rather than to in-
volve the patient in the unnecessary suffering and the final
disappointment which may follow from lack of judgment in
the selection of a proper time.

If it is wrong to risk an operation during the prevalence of
grìppe, what shall be said of the lack of judgment which
permits one while the patient is in the midst of an attack? The
records of neurasthenia would probably furnish an
emphatic reply.

Fortunately, the season of influenza is practically past,
but there is another which is about to appear—namely, that
of hay fever. Unnecessary as it should be to say so, it still
seems desirable to warn against the surgical treatment of
this disease during the summer months. All that has been
said with regard to influenza is true of hay fever. Any
operations done in such cases should be performed long
enough before the expected attack to enable the parts to
have fully healed, and, if possible, to have resumed as nearly
as may be a normal condition. The same results which
follow operation upon a patient who becomes the victim of
grìppe will follow, under similar conditions, in hay fever.
Discretion in these matters, even though it may occasion
the loss of an operation now and then, will certainly in the
end result to the advantage of all concerned.

1 East Thirty-third Street.
point remained normal, as was determined by the reading of very small test type. Though the mydriatic action is quite rapid and powerful, still the pupil never entirely fails to react toward light.

After a single application of this combined solution to the eye the pupil begins to dilate on an average within eight minutes and a half (varying from six to thirteen minutes), and attains its maximum dilatation within half an hour; the average being thirty-four minutes, varying from twenty-three to forty minutes. Within an hour after the application the pupil slowly begins to contract, and after the lapse of from four to six hours has again attained its normal size. The greatest dilatation continues for about half an hour, varying from fifteen to forty-five minutes, the average being twenty-nine minutes. At the maximum dilatation the pupillary diameter measures from five to six millimetres (average, 4.5 to seven millimetres), which is sufficiently large for diagnostic purposes. The three following figures show the action of the two mydriatics, homatropine and ephedrin.

The diameter of the pupil was taken in each case as strong light fell upon the macula lutea. If the light impinges upon more or less peripheral parts of the retina and not upon the macula lutea, the diameter of the pupil reaches as high as nine millimetres, and sometimes even more. The effects of the ephedrin were considered as passed off when, upon the egress of rather intense light, the pupil contracted down to its normal size. Certain it is that even when the eye was subjected to a very moderate light the pupil was a trifle larger than an eye not treated with the above-given solution. For this reason the period of time which it takes for the effects to entirely wear off vary considerably. For instance, de Vriere found a return to the normal width all the way in from five to six hours; Groenouw, as early as four hours after the instillation of a ten-per-cent. ephedrin solution.

In the use of a solution of five per cent. ephedrin and 0.05 per cent. homatropine this action was much slower, and caused no irritation, as sometimes the stronger solutions do. With this strength the pupil began to dilate as early as with a ten-per-cent. solution—i.e., eight minutes and a half after the first application—and a full mydriasis was obtained within forty minutes. The return to the normal width began a trifle sooner, usually after fifty-six minutes, while the entire influence had passed off after a lapse of three hours and a half. The maximum dilatation continued for twenty minutes, and this dilatation is as great, as experiments have shown, as that resulting from the use of a ten-per-cent. solution.

In the use of a one-per-cent. homatropine solution the mydriasis takes place much later than by the use of the combined solution—i.e., fourteen minutes—and attains its maximum much later, and continues for about twenty-four hours. This is obvious from Fig. 3.

The ten-per-cent. solution of ephedrin does not show any marked difference from the combined solution—i.e., no difference with reference to the beginning of mydriasis, its maximum point, and the time necessary for the return to a normal condition. The greatest difference between the two solutions exists in maximum dilatation. By the use of the combined solution the pupil is dilated from one to two millimetres more than by the ephedrin solution; hence the mydriatic power of the ephedrin is greatly increased by a trifle of homatropine. Then, too, the combined solution of ephedrin and homatropine does not deteriorate as rapidly as homatropine, a solution of the former three months old showing no sign of loss of action.

Figs. 1 to 3 show a few typical curves of the action of the various solutions—ephedrin, ten per cent., homatropine, 0.1 per cent. of each solution three drops were instilled. The rather irregular curves result from the inability to exactly measure the pupil diameter, and are not to be ascribed to the action of the drugs.

The curve for the ephedrin-homatropine solution is rather rapid in rising, a somewhat short climax, and a gradual decrease to the normal. The curve for the ephedrin is similar to the above, with the exception of not attaining so high a climax. The curve for the homatropine begins to rise somewhat later, but in a similar manner, while the combined solution reaches a trifle higher point and remains there for a longer period of time.

From the above remarks it can be seen that we possess in the ephedrin-homatropine solution practically an ideal mydriatic for diagnostic purposes, being rapid in its action, sufficiently intense, and of very short duration.*

Change of Address.—Dr. J. H. Ganzler, to No. 345 East Eighty-sixth Street, New York.

* Merck prepares this solution under the name of "mydrin."
A CASE OF PEMPHIGUS PRURIGINOSUS.

By R. S. DUBS, M. D.,

CHICAGO.

In the New York Medical Journal of January 5, 1895, I reported upon a case of chronic haemorrhagic pemphigus. The patient, whom I have quite recently seen, is enjoying good health, has fully regained his former body weight, but is troubled, however, with the occasional appearance of eruptions. These invariably pass away quickly, it being usually enough to remove the uplifted part of the epidermis, the remaining part being sufficient to prevent further exudation. A few weeks after the appearance of my communication I was called in to the case to be described. As in the former case, so here, the patient had been in the hands of a number of physicians successively.

History.—The patient, Mrs. H. S., is a very corpulent lady of seventy-one years. Both her parents lived to be seventy years old; her father dying of “asthma complicated with dropsy,” her mother from the “effects of overlifting.” She had eight brothers and sisters, three of whom died in infancy, one at the age of three months of “convulsions,” another at the age of eleven months from injuries incurred by a fall, the other at the age of three years, the cause given being “a fright.” Three sisters and two brothers are living and enjoying fair health, the eldest being seventy-eight years of age. The patient herself was born in July, 1823. Her past history she gives as follows: When eleven years old she had typhoid fever. At eighteen years she first menstruated. When nineteen she suffered several months from a “digestive trouble.” She married when twenty-two. From her thirtieth to her fiftieth year she suffered from frequent attacks of backache and headache. When forty years old she says she had typhoid fever again, from which she recovered very slowly. At fifty-one years she suffered several months from the effects of a “sunstroke.” Since that time she has enjoyed good health until last summer (1894), when her present trouble began. Of her eight children six are living, one having died at the age of eleven years of typhoid fever and one daughter at thirty-six years of “puerperal fever.” She has had no miscarriage or premature births. The six children who remain are all married and have families. With the exception of one lady who suffers greatly from rheumatism, they are quite healthy in appearance.

From this history we can glean nothing which could throw light upon the present disease. It is perhaps worthy of note that her digestive tract was most frequently the part affected by disease, and, in fact, she says that for the last ten or twelve years she has been troubled with “pyrosis” almost constantly.

Her present disease she describes as follows: In July, 1894, she noticed a frequent appearance of eruptions just like “mosquito bites” upon the inner sides of her wrists. These never remained longer than one or two days, when they would disappear; but while they lasted intensely, the sensation being often more like “burning.” At their appearance the forearm would feel hotter than usual and the region of the wrists would be reddened and slightly swollen. In November these eruptions, which till then had appeared upon the forearm only, suddenly appeared upon the inner side of the thighs also, the symptoms being precisely the same as when upon the wrists. Early in December, in addition to these eruptions upon the wrists and thighs, an intensely itching rash, much like “measles” in appearance, spread over the abdomen and back. About two weeks later, the middle of December, the limbs about the knees, her breasts, and her upper arms near the shoulders began to swell, the skin of these parts assuming a red, glossy color, but being interspersed here and there with lighter spots. One afternoon, toward the latter part of December, she was suddenly taken with chills and fever and forced to take to her bed. In that night there appeared a great number of large watery blisters about the size of a silver dollar upon the upper arms and about the ankles on the lower limbs. In the course of a week the blisters spread over the whole body, several frequently uniting so as to form one, so that in some places spaces about the dimensions of the palm of the hand were covered by one such large blister. This state of affairs continued until I took the case.

To recapitulate shortly: From July, an oft-recurring papulous eruption on the flexor sides of the forearms; in November, a like eruption upon the thighs; in the beginning of December it spread over the greater part of the body; toward the end of this month, with chills and fever, a bullous eruption on the limbs which rapidly extended over the whole body.

Status Present.—Patient is somewhat below the medium height, has well-developed muscles and a great superabundance of adipose tissue. She lies upon her back with the head and chest somewhat elevated and her arms and legs distended. She has a restless, frightened look, one betraying suffering and pain. The face is slightly flushed, rounded, and full. The pulse is accelerated, regular, moderately strong, but small. The breathing is faster and more superficial than is normal. The marked symptoms are the swollen, reddened skin and the eruptions presently to be described. The temperature is slightly increased only, the percussion boundaries of the heart are not beyond the normal, its tones clear and distinct. The lungs are also in a normal condition. With the exception of frequent ructus and pyrosis there is no disturbance of the digestive tract. The urine is decreased in quantity, about twelve hundred cubic centimetres, highly colored, clear, 1·024 specific gravity, of acid reaction. There is a small amount of albumin present. Urobilin and bile pigment tests are negative. The indican reaction, however, is very marked. By adding to the urine an equal amount of hydrochloric acid, then a few drops of a freshly prepared solution of chlorinated lime and shaking, indigo blue is precipitated in flakes. The reflexes are all quite normal, and save the excited state of the patient there are no symptoms on the part of the nervous system. This continual irritation no doubt will explain the accelerated pulse and rate of breathing.

On the right arm the skin was infiltrated (swollen), red, glossy, and hot to the touch. The swelling was not uniform throughout, but there were interspersed many areas of apparently healthy skin, the niveau of the affected parts being fully five millimetres above that of the healthy skin. Upon the dorsum of the hand were some half a dozen facelid bullae about the size of a nickel five-cent piece. The palms of the hand were free from any eruption. On the forearm were many bullae, some larger than those on the dorsum manus, especially those on the flexor side. The skin in the region of the elbow was uniformly reddened, swollen, shining, and under quite a tension, there being few eruptions here. On the upper arm near the shoulder were the largest bullae, they being fully twice the size of a silver dollar and from three to four centimetres high, though half distended with fluid only. Wherever these eruptions had burst or been opened there would be found shrunken epidermis and dried exudate, which together gave the appearance of large, rough seeds. This was especially the condition upon the flexor side of the forearm. The contents of the eruptions were somewhat changed after a time; at first a clear, light-yellow-colored fluid, later, if not opened, a sort of gelatinous substance, which could often be separated into layers. If the clear fluid of a fresh bulla was caught up it invariably clotted. The swol-
len skin, the large number of bullous eruptions, the partially adherent scabs, all united to make every movement painful (which was doubtlessly increased by the impressions the patient received through the optic nerve). The left arm presented a similar appearance to the right. The lower limbs were most severely affected below the ankles, the dorsum of the left foot being taken up by one large bulla. The trunk presented a more uniform redness than did the limbs. From the umbilicus to the ensiform process, and laterally to the posterior axillary lines, was a space of healthy skin which was separated from the diseased surroundings by a distinct, elevated, reddened wall. Some parts of the abdomen presented the appearance of an urticaria gyrata, there being so many islets of healthy skin scattered through the diseased parts. Sparingly scattered over the trunk were bullae varying in size from that of a five-cent piece to half a dollar. In the mouth, nose, ear, vagina, or rectum I could discover no eruptions nor see any signs of the same (infiltration, etc.). When the patient's age is taken into consideration, the extent to which the disease had spread—the whole body, save the face and neck, the palms of the hands, and feet being affected—it is quite easy to picture the patient's nervous condition. In truth, for the first week of treatment this needed the most careful attention.

Treatment. —It was essentially that described in my former article (vide New York Medical Journal, No. 1, 1895). To insure a more rapid effect, arsenic was at first administered hypodermically—the sodium salt of arsenious acid—later, the Asiatic pill being used. In this case I gave larger doses, too; at the height of the treatment, 0.94 gramme a day. Externally the present treatment varied in no respect from that in the former case till later on in the sickness. The disordered stomach readily yielded to a carefully directed treatment with such simple remedies as hydrochloric acid and pepsin. As the dose of arsenic increased, the indelicate reaction in the urine got weaker, finally to disappear, doubtless due to the antiseptic properties of arsenic.

Fourteen days sufficed to cause the exudation in the skin to disappear; in this time all the redness and swelling above described had passed away. This took place gradually, at night these symptoms always being most marked. After the treatment was well under way the evening exacerbation was always less than on the previous day, until it had wholly disappeared.

With few exceptions, the places denuded of their epidermis (some in part, others wholly) rapidly healed. The extensor side of the leg, over the tibia, and the flexor side of the forearm, over the tendons, caused some trouble. No sooner had the several eruptions disappeared when new ones would appear; but a patient repetition of the external treatment conquered. I should like to lay stress upon the necessity of promptly removing the whole of the uplifted epidermis as soon as a bulla arises. If this is not done it causes the patient great pain, and the parts beneath ulcerate more quickly than the whole cutis is destroyed—e.g., upon the dorsum of the left foot upon removing the larger eruption above mentioned, and the jellylike mass which is always found in those of longer standing, the extensor hallucis longus tendon was exposed for the distance of an inch or more.

This case varied in some respects from the former. After the eruptions had disappeared and the skin regained its pliability there occurred frequent eruptions of herpes. I noticed such in the region of the cutaneous branch of the right ol
turator nerve, on either side of the thorax and abdomen, in the district of the lumbar intercostal nerves especially, and once in the region of the left axillary nerve. It was, with few exceptions, an abortive zoster, a papulous eruption merely, vesicles not being formed. The sensation was described as one of prickling and burning, and was best relieved by the free application of cool, moist cloths covered with a layer of impermeable ma-
torial. Herpetic eruptions have been described as due to arsenic; whether that was the case here I could not say, deeming it better not to discontinue its use, seeing the disturbance was of short duration (one to three days only in the various cases) and the ascribed cause quite problematical. Similar outbreaks have appeared seven weeks after all treatment with arsenic had ceased.

Long after the rest of the skin was in a nearly normal condition there remained at the roots of the phalanges on the dorsum of the hands and on the dorsum of the feet small, hard, slightly reddened, intensely itching—exacerbating nights—knots in the skin. Sarcoptes scabiei was searched for in vain, though they disappeared in a week's time on the application of unguentum cinerereum.

Again, at times there would suddenly appear on the flexor sides of the forearm an eruption of dark red, circumscribed, slightly elevated "papules." When this took place the forearm would first swell some and the skin on the affected side become red, hot, and slightly edematous, which symptoms always preceded such an outbreak by six or twelve hours. The appearance of these eruptions, as well as their size—from two to five millimetres in diameter—were quite different from the herpes above mentioned. They never extended into the upper layer of the epidermis, for this as a slightly shriveled layer passed directly over them, and could frequently be removed in small sheets without affecting either them or the skin between them. Then, too, they remained longer and withstood almost every remedy. Resorcine gave the best results, but I would warn against its use in a too concentrated form.

Upon the forearms and upon the abdomen—parts which had been more severely affected—I noticed a profuse eruption of "milia." They caused none but a cosmetic disturbance. In size about as large as a pin-head and situated in the epidermis, the superficial layer passing intact over them, they could easily be removed with a pin or needle without causing pain or any flow of blood.

Pemphigus is characterized by the continuous appearance of bullae upon the skin and mucous membranes. It is, in the full sense of the word, a chronic disease, an acute eruption of bullae, such as at times is seen upon the basis of an eczema, etc., being more fittingly termed dermatitis bullosa. Pemphigus may begin acute, but its chronic character is ere long discovered. According to the most marked symptoms it has become customary to classify the cases of this disease. We speak of pemphigus vulgaris when there is a continued eruption of bullae upon a normal or reddened skin. Should the contents of these eruptions, instead of being light yellow in color and clear, contain blood, we call it pemphigus haemorrhagicus. In those cases where, after the bulla has burst and the scab, consisting of shriveled epidermis and exudate, has fallen off, a new scab is continually formed—partly dried-up exudate, partly dead epidermis, this being kept up upon the site of the bulla—we speak of pemphigus foliaceus. Should the sites of the bullae become the seat of a rapid granulating growth, it is termed pemphigus vegetans. When the bullae appear upon an urticaria eruption which causes intense itching, we speak of pemphigus pruriginosus. The case above described would, according to its symptomatology, be put under the last head.

Having twice tested the above given treatment for pemphigus, and with the best of success in each case, I can
warmly recommend the same. Though my method of treat-
ment be somewhat cumbersome, still it gives ample returns
in that the patient is soon to a great degree relieved of pain,
and in that the progress of the disease is restricted and the
existing eruptions caused to disappear.

612 LINCOLN AVENUE, CHICAGO, ILL.

TETANY:
WITH THE REPORT OF A TYPICAL CASE.*

By GEORGE J. PRESTON, M.D.,
PROFESSOR OF PHYSIOLOGY AND DISEASES OF THE NERVES SYSTEM,
COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

If, along with the name, we accept the description of
tetany given by Trousseau, Dane, Corvisart, Steinheim,
and other writers of fifty years ago, then it is a very rare
disease. Of late years it has been the tendency to include
under the head of tetany many different varieties of mus-
cular spasm. It would seem best either to restrict the
term tetany to cases presenting the classic symptoms or to
discard the name altogether and class all cases presenting
such symptoms under the general term of muscular spasms
of unknown origin. While this affection is not uncommon
on the continent of Europe, it is rare in England, and ap-
parently still more rare in this country. The disease, if we
may call it a disease, may appear at any age, but is far
more frequently seen in childhood and youth. Apart from
the tetany of lactation, the true disease is very rarely met
with in the adult. The classic symptoms are too well
known to require any detailed description. Sometimes
there are slight prodromal symptoms, such as numbness
or tingling in the extremities, with some slight disturbance
of motion. Then comes the tonic convulsion, which begins
usually in the upper extremities. The thumb is strongly
adducted; the fingers are pressed closely together and semi-
flexed over the thumb; the hand becomes conical in shape,
assuming the form called by Trousseau the "acceoucher's
hand." The wrist is next involved, being turned in. The
forearm may be slightly flexed upon the arm. In the
lower extremities the toes are bent toward the sole, the
great toe being turned under the others, and the sole of the
foot hollowed out. The heel is pulled up, the leg and
thigh being in a state of extension. The muscles are
firmly contracted and resist efforts to overcome the con-
traction. The above is in brief the description given by
Trousseau.

Occasionally the lower limbs may be involved first, or
one side may be chiefly affected. In severe cases the con-
traction may involve other muscles, the diaphragm, osoph.
agus, larynx, muscles of the back and neck, producing
opisthotonous, and very rarely the facial muscles may be af-
fected. The attack generally lasts but a few minutes,
relaxation comes on, and there are no symptoms during the
interparoxysmal state. In some cases the tonic spasm may
continue for hours or days, though it is doubtful whether
these cases should be called tetany. The attacks recur

* Read before the Medical and Chirurgical Faculty of Maryland,
April, 1895.

with greater or less frequency for months or even years.
The frequency of the attacks varies very much; in some
cases they occur only three or four times daily, in others
every few minutes. The following case conforms almost
perfectly to the classic descriptions of tetany:

The patient, a girl of three years and a half, was referred to
me by Dr. George Strauss. The family history was perfectly
good, and the child had always been healthy. There was not
the slightest evidence of rickets. Physical examination was
negative, and the child seemed very intelligent. When she
was one year of age, or two years before I saw her, she had the
first attack. There would be months in which she was per-
fectly well, and then the attacks would come on for no apar-
ent reason. While in my office she had an attack, beginning
almost simultaneously in hands and feet. Her hands assumed
the typical form described above—wrist and elbow slightly
flexed. The legs were extended, heels raised, and feet slightly
inverted. Upon inquiry during the attack she said she had no
pain, and except for the fact that she had to stop her play her
father said she did not seem to mind the attacks. There was
no involvement of the facial or other muscles. After a few
moments of tonic contraction the attack passed off. At the
time when I saw the patient she was having from ten to fifteen
attacks daily. There was no anesthesia and the reflexes were
unaltered. Pressure upon the inner side of the arm or at the
bend of the elbow would bring on an attack.

This I take to be a typical case of tetany, and I would
be inclined to restrict the name to cases presenting in gen-
eral such symptoms. So many different affections have
been called tetany that it is difficult to arrive at any definite
knowledge as to the frequency of the disorder. Griffith
has collected all the American cases up to 1894, in number
seventy-two. A cursory glance at these cases, as he has
abstracted them, will show that many of them do not be-
long under the name of tetany. In this list are what would
seem to be meningitis, trauma, hysteria, and simple mus-
cular cramps. Thus it will be seen that tetany is a very
uncommon affection in this country, although it is not rare
on the continent.

Among the symptoms of tetany may be noted a curious
increase of electric excitability; this is so marked that an
anodal opening tetanus can be obtained. Chvostek has
called attention to the fact that pressure over the facial
nerve at its exit from the foramen will produce contraction
of the facial muscles. The question has been raised but
never definitely settled as to whether the Trousseau sign is
produced by pressure on the artery or the nerve. The
altered electrical reaction would rather point to the latter
as the most probable factor.

The two interesting questions concerning tetany are,
first, whether it is a sufficiently distinct affection to be
separated from the many other forms of muscular spasm,
and, second, what is its probable cause? In regard to the
first of these questions it may be said that so long as our
knowledge of the nature of the disease is so uncertain it is
best to hold to the clinical differentiation. The symptoms
of such a case as the one related are certainly sufficiently
distinct to give it at least a clinical place.

With our present knowledge of tetany it is impossible
to do more than speculate as to its cause. The symptoms
point to the spinal cord as the seat of the disease rather than the brain.

The four extremities are practically always involved, and when this is not the case the two upper extremities are affected. Tetany involving one side is very rarely if ever met with. Both motor and sensory nerve elements are involved, and decided trophic symptoms have been noted. A curious fact is the occurrence of tetany after the removal of the thyroid gland, Wolffier having noted it seven times in seventy operations. In this connection it might be noted that both in tetany and Basedow's disease the electric excitability is greatly exaggerated.

Of the many causes to which the disease has been attributed, the most important seem to be diarrhea and exhausting diseases generally, and in adults lactation and exposure to cold and wet. The theory that all cases are rachitic is not borne out by observation. The causes above mentioned are just the ones that a priori we would expect to affect the nerve cells, perhaps using up their protoplasm. Again, the recovery from the disease may be rapid or, on the other hand, very slow, which, according to this theory, would mean that the protoplasm of the spinal nerve cells was only slightly or very markedly involved, these latter cases giving rise to nutritive disturbances. The autopsies that have been made by Trouseau and others are of no value whatever; certain spots of softening and the like are claimed to have been noted, but they were probably post-mortem changes.

The course of the disease is very variable, showing a tendency to reappear after months or even years of absence. It is comparable in this respect to chorea vulgaris, though of longer duration. Gowers quotes several cases of tetany occurring in successive pregnancies, and Osler refers to a similar case (Trans. Am. Assoc. of Physicians, 1894). The prognosis is practically always favorable, only a few doubtful cases of death having been reported. The diagnosis presents no special difficulties if we restrict the term tetany to those cases that present the classic symptoms. Petit mal, tetanus, organic brain disease, and hysteria are the affections most likely to be confounded with it. It is not likely that true tetany is often mistaken for hysteria, but the opposite mistake probably frequently occurs. One feels convinced in reading many of the cases reported as tetany that the condition was hysteria. The unilateral character of hysterial contractures and the presence of other stigmata are usually diagnostic. The treatment may be summed up in a few words: Good hygiene, proper diet and exercise, the bromides and electricity, and perhaps local applications. Chloroform applied locally seems to have a good effect, as does iced to the spine. I have ventured to bring this case before the notice of this society in the hope that more cases of this rare and interesting affection will be observed and reported.

The Salicylate of Sodium in Ophthalmia.—A solution of the salicylate of sodium, of the strength of ten grains to the ounce and upward, is highly recommended by an occasional contributor as a collyrium in simple ophthalmia. When frequently applied the effects are quickly manifested.

NEURITIS.*

By F. H. STEPHENSON, M.D.,
MEMBER OF THE NEW YORK STATE MEDICAL ASSOCIATION.
CENTRAL NEW YORK MEDICAL ASSOCIATION,
SYRACUSE ACADEMY OF MEDICINE.

I wish to call your attention to the subject of adventitial or isolated neuritis, as illustrated by four cases under treatment by me, of which I shall give brief sketches:

Case I.—Jennie B., ten years of age, has had the simple diseases of childhood. Her family history is negative. She has sore throat frequently. After each attack she is lame in her left limb and has pain on extending the heel to the floor; she also limps. After an illness she walks first on the left toes. There is now no difference in the temperature of the two limbs; there is a slight atrophy in the affected limb, but no pain on moving the foot or knee joint, or on pounding on the bottom of the extended foot and limb, such as would occur in the hip if the disease were there. The knee-jerks are normal; there are no changes in sensation. The faradise responses are good on the right side; the tibialis anticus responds with stronger current on the left side. The posterior group responds well.

The etiology is a great aid to the diagnosis of this disease.

Diagnosis.—Probably ataxic neuritis of diptheritic origin, as a history was given of frequent sore throats.

In diptheritic paralysis there is often a symmetrical neuritis, which was formerly thought to be always due to spinal-cord disease. But in this case we have healthy action of all but a single group of muscles.

These cases of diptheritic neuritis are sometimes taken for poliomyelitis. But in poliomyelitis we have loss of the reflexes, marked atrophies, and the reactions of degeneration; in them the onset is also very acute and usually painless. In neuritis the course of the disease is different: we have pain, tenderness over the course of the inflamed nerves, decided paralysis in the distribution of the nerve, and other symptoms which will be enlarged upon in the cases which follow:

Case II.—Mr. W., aged fifty years. He was driving a fraction of team of horses in winter, and wore a pair of tight kid gloves. The seam about the thumb pressed to a somewhat painful extent against the terminal filaments of the median and radial nerves. The thumb became intensely cold and painful, which caused him to think he had frozen it. The pain was only partially controlled by artificial heat, rubbing, and wrapping in flannels. Physicians were consulted, who treated him for a sprain, for rheumatism, and gout. Electricity was used—both galvanism and faradism; also baths at Clifton were resorted to. When the patient was referred to me, the disease had continued for over three months. The patient was unable to dress himself or to use the hand in any way without extreme pain. If it became at all chilled, he also suffered. The skin presented a shining appearance and was extremely tender over the course of the nerves. Some of the same symptoms, only to a less degree, extended to the first finger and part of the second.

My diagnosis was neuritis from cold. I first ordered absolute rest of the arm, having it bound in flannel and carried in a sling. Sometimes it is even necessary for a patient to remain in bed, to avoid the slightest movement, as the muscuar contractions over these nerves are a source of constant irritation.

* Read before the Onondaga Medical Society, February, 1895.
and pain. I gave this patient three grains of sodium salicylate and two grains of quinine, four times daily; also applied galvanism, applying the anode over the painful part of the nerve, giving daily sittings of about twenty minutes' duration. This patient made a complete recovery in about four months, and for two years has had no return.

Case III.—Miss G., while crossing the street, slipped on the ice and fell on the street-car track, striking the sciatic nerve. She was dazed and helpless, but in a few moments was able to move with assistance and was driven home. A physician was called, who prescribed liniments, which she used for a month with little benefit. When I was called to see her I found the sciatic nerve swollen and extremely tender. The limb had wasted, and she was scarcely able to move, experiencing constant and extreme pain when attempting to do so, and walking in a manner resembling that of a person affected with tabes.

This patient was put to bed and artificial heat applied, as her condition seemed rather to suggest heat than cold, although Champion's spinal ice bags are perhaps now used with greater benefit than hot applications in sciatic neuritis. Galvanism and internal medication were employed, as in Case II. This patient made a complete recovery in about four weeks. Last year she fell and struck the opposite limb in the same manner with the same symptomatology. After the course of treatment already mapped out had been employed with but little improvement, blisters were applied with some benefit. Deep-seated injections of from five to ten minims of a one-per-cent. solution of osmic acid were given once daily for three or four days. The pain had to be controlled by morphine, which many times only seemed to relieve when given hypodermically.

Deep cocaine injections are recommended, but they are only of temporary value. Nerve-stretching I have not been obliged to resort to, nor should I wish to except in a very extreme case, as paralysis sometimes follows such an operation.

Many cases of neuritis presenting ataxic walks and diminished knee-jerks with sluggish reflexes are mistaken for tabes. When the patients are cured they are reported as cases of tabes, when really they were only cases of neuritis. Fully ninety per cent. of cases of neuritis result from cold. The inflammation in a majority of these cases is in the sheath of the nerve, and a deposit is formed which presses on the nerve substance. In more severe cases the nerve tissue or substance is involved.

The symptoms of neuritis vary extremely according to its intensity, its extent, and the nerve that is affected. The chief symptoms are local. The most prominent is pain felt in the inflamed part of the nerve, and also often in the part to which it is distributed. Sometimes the pain involves the whole limb, and in severe cases it may be most intense, burning and boring, but rarely darting, in character: "a little devil boring away!" as one of my patients recently expressed it. The pain is increased by movement, by postures that involve tension or pressure of the nerve, and by whatever causes passive congestion of the limb, such as the act of coughing. Sometimes it seems to radiate into distant parts, and pain is often also felt in the corresponding region of the opposite limb. The sensitiveness of the affected region is increased, and even the bone may be tender, so that at first attention may not be directed to the nerve, but when this is pressed great pain is always produced. In slighter cases the pain is usually limited to the nerve and its distribution. If the nerve is accessible to direct examination it may sometimes be felt to be distinctly swollen at the affected part. Occasionally the skin over it is observed to be red. The muscles supplied by the nerve become weak in various degree and tender, and present fibrillar twichings. They are seldom powerless, but pain may prevent their contraction. They present the altered electrical reactions characteristic of nerve lesions. Sometimes eruptions occur; in some cases the epidermis thickens, as in ichthyosis; again, atrophies occur, as glossy skin. Constitutional disturbance subsides in the course of a few days. Frequently pain and other symptoms subside into a chronic stage and may continue as a secondary neuralgia.

Alterations in the nutrition of the joints occur and adhesions form, limiting the movement of the limb. The inflammation is sometimes ascending in character, attacking the spine and continuing on to the nerves of the other side of the body. Also reflected pains are occasionally felt in the opposite side of the body when there are no evidences pointing toward neuritis. The following case illustrative of this is under treatment now:

A man of seventy years fell, over three months ago, striking on the right sciatic nerve. He developed a typical neuritis, with the symptoms already enumerated, although for some weeks he had been treated for a strain, with liniments, etc. The opposite limb began to develop reflex pains, with some weakness and tenderness, simulating neuritis very closely. Under treatment the symptoms subsided more rapidly than on the injured side. The patient is still under treatment and promises a fairly good recovery.

A slight acute neuritis may run its course in a few weeks and then subside. Much more commonly the affection persists in a chronic stage for many weeks and months. The diffuse pains that attend the onset may be mistaken for the pains that attend acute rheumatism, but in the course of a day or two the localization of the symptoms declares their nature.

Chronic neuritis is easily often mistaken for neuralgia; but let us compare sciatic neuralgia and sciatic neuritis. In sciatic neuralgia we have some painful points along the nerve, intermittent pain, no loss of power, as a rule, except from pain, no atrophy, and no electrical changes; the reflexes are normal, and there is no loss of sensation; while in sciatic neuritis we have usually the entire nerve tender and painful; there is constant pain, decided paralysis in the distribution of the nerve, atrophy, electrical, sensory, objective, and subjective changes, and the reflexes are often diminished or lost. In both of these conditions, although the symptoms and clinical appearances differ, the treatment is quite similar. But one thing is absolutely imperative—viz., complete rest of the member, regardless of whatever medication is employed. If this precaution is not taken, disappointment is sure to follow any treatment.

The Appleton Prize, consisting of twenty-five dollars' worth of medical publications, offered annually by the firm of D. Appleton & Co. to the candidate passing the best examination before the board of medical examiners of the State of South Carolina, was won this year by Dr. Jenkins M. Pope, of Charleston.

NEW YORK, SATURDAY, JUNE 8, 1895.

MEDICAL CENTRES.

The degree of importance attained to by any particular centre of medical teaching is justly held to be dependent in great measure on the excellence with which it does its work, on the abundance of its clinical resources, and on the adequacy of its equipment in the way of laboratories and the like. But this is by no means the whole story. A certain large city becomes the medical centre for a pretty definite area of country, and with little variation continues for long periods of time to perform its function accordingly. It would be interesting to have the data so displayed as to show graphically in detail the territories tributary to the various great centres of medical teaching in the United States, but at present we must content ourselves with a few examples shown in a very general sort of way. Thus, Boston seems to draw its students mostly from its own immediate vicinity, from Maine, from New Hampshire, from the eastern part of Massachusetts, from Rhode Island, and from the northeastern part of Connecticut; New York is resorted to from Vermont, the whole State of New York, the western part of Massachusetts, nearly the whole of Connecticut, the northern part of New Jersey, the northwestern portion of Pennsylvania, and Ohio and Indiana; Philadelphia draws from the greater part of Pennsylvania, from the southern portion of New Jersey, and from the Southern States almost indiscriminately; Chicago serves for the whole Northwest; and St. Louis, Louisville, New Orleans, and Atlanta are the centres for the Southwest and South, exclusive, in the case of the South, of the element that is attracted to Philadelphia. The few notable changes that have occurred of late years seem to be Boston's loss of its former large quota from the eastern British Provinces and Philadelphia's comparative loss of southerners.

It will be seen that the areas here indicated correspond very closely with those from which the various cities mentioned draw their domestic commerce, and the inference is unavoidable that geographical considerations quite outweigh all others in leading the medical student to decide upon the city in which he will take his courses—not, indeed, as regards individual schools and not in all instances as regards even the general question, for every considerable medical school in the country has students from all quarters of the land. A city's commercial importance enhances its attractiveness as a centre of medical teaching, and naturally the territory in which that attractiveness is most potent is the same as that in which it is commercially the most prominent. In so far as the student deviates from governing himself by ideas of commercial supremacy—meaning local supremacy—he is apt to take into view solely the reputed excellence of particular schools, and this seems to be the reason why those cities that have the best schools are steadily gaining in the number of students that resort to them. It is easy to see that this will come to be more and more operative year by year, and that the different cities must keep on advancing their standards or lose their relative status as centres of medical education. The spirit of rivalry will thus be kept alive, and its action will be in every way beneficent.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending June 4, 1895:

State Medical Examining and Licensing Boards.—A permanent national organization of the various State boards was effected at the recent meeting of the American Medical Association at Baltimore. Officers were elected for the ensuing year as follows: President, Dr. W. W. Potter, Buffalo, N. Y.; vice-president, Dr. J. M. Hays, Greensboro, N. C.; secretary, Dr. B. M. Griffith, Springfield, Ill. Committee to draft constitution and by-laws: Dr. Charles McIntyre, Easton, Pa.; Dr. W. W. Potter, Buffalo, N. Y.; Dr. N. Payne, Albany, N. Y.

The purposes of the association are to establish a uniform schedule of requirements for all medical colleges and examining boards, and to assist in perfecting a method for higher medical education.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 13 to June 1, 1895:

RICHARD, CHARLES, Captain and Assistant Surgeon, when relieved from duty at the Military Prison, Fort Leavenworth, Kansas, will proceed to and take station at St. Louis, Mo., for duty as attending surgeon and examiner of recruits.

EGAN, PETER R., Captain and Assistant Surgeon, is relieved from duty at Fort Custer, Montana, and ordered to Fort Assiniboine, Montana, for duty, relieving BYRNE, CHARLES, Major and Assistant Surgeon. Major Byrne, on being thus relieved, is ordered to Fort Snelling, Minnesota, for duty.

SHANNON, WILLIAM C., Major and Surgeon, is ordered to Fort Custer, Montana, for duty upon the expiration of his present leave.

HOWARD, DEANE C., First Lieutenant and Assistant Surgeon, will be relieved from duty at Fort Snelling, Minnesota, upon the arrival there of BYRNE, CHARLES B., Major and Surgeon, and will then proceed to Fort Custer, Montana, and report for duty at that post.
Chapin, Alonzo R., Captain and Assistant Surgeon, by direction of the President, is retired from active service this date, May 10, 1895, having been found by an army retiring board incapacitated for active service on account of disability incident to the service.

Wakeman, William J., Captain and Assistant Surgeon, is granted leave of absence for four months, to take effect on being relieved from duty at Fort Thomas, Kentucky.

Gibson, Robert J., Captain and Assistant Surgeon, will be relieved from duty at Fort Sam Houston, Texas, by the commanding officer of that post, and will report in person to the commanding officer at Fort Thomas, Kentucky, for duty at that post.

Gardner, William H., Major and Surgeon, is relieved from duty as attending surgeon and examiner of recruits at Head-quarters Department of Dakota, and ordered to Fort Reno, Oklahoma Territory, for duty at that post, relieving Cronkhite, Henry M., Major and Surgeon. Leave of absence for four months, on surgeon's certificate of disability, with permission to leave the Department of the Missouri, to take effect on being relieved from duty at Fort Reno, Oklahoma Territory, is granted Major Henry M. Cronkhite, Surgeon.

Crampton, Louis W., Captain and Assistant Surgeon, is granted leave of absence for ten days, to take effect from the date of the conclusion of his examination for promotion.

Wilcox, Timothy E., Major and Surgeon, is granted leave of absence for one month and fifteen days, to take effect on his arrival in New York city, en route to his station in the Department of the East.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending June 1, 1895:

Walton, T. C., Medical Inspector. Ordered to examination preliminary to promotion as Medical Director.

Bearssley, G. S., Kidders, B. H., and Van Reefen, W. K., Medical Directors. Ordered as a board to examine medical officers for promotion.

Bates, L. M., Medical Director, Flint, J. M., Medical Inspector, and Gatewood, J. D., Passed Assistant Surgeon. Ordered as a board to revise the book of instructions for medical officers.

Society Meetings for the Coming Week:

Monday, June 10th: New York Ophthalmological Society (private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Lenox Medical and Surgical Society, New York (private); Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

Tuesday, June 11th: Delaware State Medical Society (first day—Wilmington); Massachusetts Medical Society (first day—Boston); New York Medical Union (private); Kings County, N.Y., Medical Association; Medical Societies of the Counties of Chenango (semi-annual), Erie (semi-annual—Buffalo), Genesee (annual—Batavia), Oswego (annual—Mexico), Rensselaer, Schoenectady (semi-annual—Schenectady), Warren (annual—Lake George), and Wyoming (Warsaw), N.Y.; Newark (private) and Trenton, N.J., Medical Associations; Clinical Society of the Elizabeth, N.J., General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Ky.

Wednesday, June 12th: Kentucky State Medical Society (first day—Harrodsburgh); Delaware State Medical Society (second day); Massachusetts Medical Society (second day); New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Metropolitan Medical Society, New York (private); Medical Societies of the Counties of Albany, Dutchess (semi-annual—Rough Pence), and Montgomery (semi-annual—Fonda), N.Y.; Middlesex, N.J., County Medical Society (annual); Rhode Island, R.I., County Medical Society (annual—Providence); Philadelphia County Medical Society.

Thursday, June 13th: Kentucky State Medical Society (second day); Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; Medical Societies of the Counties of Cayuga, Cortland (annual), and Fulton (semi-annual), N.Y.; New York Laryngological Society; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

Friday, June 14th: Kentucky State Medical Society (third day); Medical Society of the Town of Sangerties; Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn.

Saturday, June 15th: Clinical Society of the New York Post-graduate Medical School and Hospital.

Answers to Correspondents:

No. 436.—We fear you are in search of what is not likely to be found—a trustworthy medicinal depository that is permanent in its action. In your use of the depilatories of which the formula are given in the text-books, you may not have had the advantage of having them freshly prepared. The following formula was published in the Pharmaceutical Era a few weeks ago:

- Iodine.......................... 23 grains;
- Oil of turpentine.................. 40 drops;
- Castor oil........................ 1 drachm;
- Alcohol........................... 5 drachms;
- Collodion, enough to make........ 2 ounces.

Mix. To be applied daily for three days. We can not vouch for its efficacy.

Birhths, Marriages, and Deaths.

Married.

Flagg—Walker. — In Buffalo, N.Y., on Wednesday, May 22d, Dr. John Dodd Flagg and Miss Minnie Marea Walker.

McQueen—Woodward. — In New York, on Monday, June 3d, Mr. Walter McQueen and Miss Daisy Grace Woodward, daughter of Dr. and Mrs. Corydon Woodward.

Wickes—Craig. — In New Orleans, on Monday, May 27th, Dr. Henry W. Wickes, United States Marine-Hospital Service, and Miss Josephine Craig.

Woods—Bailey. — In New Orleans, on Wednesday, May 22d, Dr. William H. Woods and Miss Octavia Bailey.

Died.

Brickhahn. — In St. Louis, on Monday, May 20th, Dr. Walter L. Brickhahn, aged thirty-four years.

Downing. — In Birmingham, Ala., on Monday, May 27th, Dr. J. W. Downing.

Helmuth. — In Chicago, on May 25th, Dr. Carl Helmuth, aged seventy-eight years.
**PROCEEDINGS OF SOCIETIES.**

**SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.**

Meeting of May 1, 1895.

The President, Dr. C. C. Barrows, in the Chair.

**Spontaneous Fracture in a Tabetic Subject.**—Dr. J. W. S. Gooley presented on behalf of Dr. Charles Phelps the bones taken from the leg of a man, fifty-six years of age, who had been admitted to Bellevue Hospital on November 19, 1894. Three years before there had been difficulty in walking at night, and he had shown inco-ordination of the muscles of the lower extremities. There had also been shooting pains in the thighs. A year before he was admitted both feet had been numb, and his right knee had been swollen but painless. He had continued to walk up to ten days prior to his admission, when a spontaneous fracture had occurred in the vicinity of the knee. When first seen he had been markedly ataxic, and not only had the knee been swollen, but there had been a tumefaction extending high up the thigh and down the leg. The skin of the thigh and leg had been dotted with ecchymotic spots. The speaker said that he had seen the patient with Dr. Phelps a few moments before the operation had been performed, and the case had appeared to him to be one of spontaneous fracture with necrosis. At that time he had not been aware of the previous history of ataxia. The specimen consisted of a little over one half of the thigh bone, on which was what appeared to be an exostosis. This patient, like the majority of ataxic patients had been probably a syphilitic subject. The fracture had occurred in the upper part of the tibia; it had been oblique, and the upper fragment had been broken into two pieces. The fracture had occurred ten days before his admission, and three weeks after his coming to the hospital amputation of the thigh had been performed. It was well known that even without a blow or fall the bones in the vicinity of the joints of ataxic patients were liable to be spontaneously fractured. This was probably what had occurred in the present instance. The upper end of the tibia was necrotic, and there had been an imperfect involucrum and some recent callus, both of which had probably formed four or five weeks before the operation. In view of the condition found the operation had been fully justified. Of course, resection had been out of the question. Partly owing to the belief on the part of some of those who had seen the patient that there might be malignant disease of the bone, the amputation had been suggested and performed.

Dr. Parker Symes said that this was the first specimen he had seen of so-called Charcot's joint, or arthropathia tabidorum. It had been maintained by many that the changes that occurred in these joints were due to traumatism. Owing to the more or less complete analgesia of the lower extremities, it was supposed that after some slight injury, such as a synovitis, the patient, not feeling any pain, had continued to use it, and as a consequence these extensive changes had taken place. Personally, it seemed to him that the pathological changes were entirely opposed to this view, and besides it was a well-known clinical fact that so-called Charcot's joints developed in the upper extremities, where analgesia was certainly not so marked, and where there would not be the traumatism that would result in the lower extremities from walking. Again, it should be remembered that these arthropathies had developed in persons while lying in bed. The bones exhibiting this arthropathy showed also the changes of osteo-malacia, and there was naturally a tendency to spontaneous fracture. In the specimen presented there had been a distinct attempt at repair, but with the fragments in a decidedly false position. When such fractures occurred in the shafts of bones so diseased they united quite firmly. For this reason he had felt that in case of Charcot's disease of the knee joint, where the joint could not be properly used for locomotion, resection might be proper. He had seen but one case in which this had been resorted to—one that had been shown before the Academy of Medicine by Dr. Willy Meyer. In this case there had been union between the divided ends of the tibia and femur. He understood that such operations had been tried abroad and with equally unsatisfactory results.

Dr. Reginald H. Sayre said that he had seen one or two of these Charcot's joints in which it had seemed to him that a traumatism had distinctly aggravated the condition. He recalled particularly one case of Charcot's ankle, with an ununited fracture just above the joint. The patient had come to him on account of what had been supposed to be an unerred sprain of the ankle. This man had had pin-point pupils and lancinating pains in his legs, with beginning heel-walk, and he had given a history of gastric crises. He had been put on antisypilitic treatment, and the ankle had been immobilized in a plaster-of-Paris boot. This treatment had been continued for about four months, and at the end of this time the eggshell cracking had disappeared from the ankle, there had been a fair range of motion in the ankle, and the size of the joint had been reduced. This man had been kept under observation for about eighteen months, and up to the time when last seen there had been no relapse. The speaker said that he had seen Charcot's joints in both toes. Such a patient had come to him under the supposition that he had had a bunion. Under antisypilitic treatment and protection of these joints they had apparently recovered. At the present time the man had what appeared to be a beginning perforating ulcer of the foot. In Dr. Willy Meyer's case of resection of the knee for Charcot's joint he had thought that the patient walked very well for a man with locomotor ataxia. Firm bony union was not always obtained in resection of the knee for other conditions. Many tubercular joints after resection, if not properly protected by mechanical support, underwent bending, showing an imperfect union. From the few cases that he had seen where tabetic joints had been protected mechanically, and from the specimen just presented, he could not see why good results should not be obtained either from mechanical treatment or from resection. It was important to remember that such accidents as spontaneous fractures be prevented.

Dr. Parker Symes said that Dr. Meyer's case had had a fall-joint, and there had been no attempt at union. The patient had seemed to him, however, to walk very well.

Dr. R. H. Sayre replied that the joint had not united, but the man had been able to control the motions of the joint in an antero-posterior direction, and there had not been sufficient lateral mobility to prevent him from walking.

Dr. Gooley said he did not think that any kind of apparatus would have answered in the case he had reported, and certainly excision would have failed. The amputation had been performed last November, and the patient was now doing well. He was surely better off with a pair of crutches than he would have been if the leg had been preserved—in fact, he felt that the patient would have probably succumbed to septicemia. A fluid had been found very closely resembling pus, although he had been told that it was not pus.
Phleboliths simulating Ovarian Carcinoma.—Dr. Frederick Holme Wiggins presented a specimen of phleboliths with the following history: Mrs. E., forty-six years of age, had had no children or miscarriages. Her menstrual life had begun at twelve years of age, and after the second year had been regular and painless. The patient had always enjoyed good health and had been a hard worker. Eight years ago, shortly after lifting a heavy stove, she had been seized with a severe pain in the right inguinal region, which had continued with more or less intensity for some months. She had then consulted him. A vaginal examination had revealed a sensitive mass posterior to and to the right of the uterus, movable, and of about the size of an ovary. Supposing it to be an ovary, the patient had been placed in the knee-chest position, and the mass had been replaced and retained by a retroversion pessary. This had given the patient relief. When next seen, on April 7th, with Dr. W. S. McLaren, of Litchfield, Conn., she had stated that last autumn, on returning to her home from a wake, she had been again seized with severe pain in the right inguinal region, radiating into her right hip and "the small of her back." With this paroxysm her bowels had moved freely, and there had been vesical tenesmus and haematemesis. The pain had lasted about six hours, and she had been relieved by the patient placing herself in the knee-chest position. The paroxysm of pain had recurred from time to time. She had been constipated. On vaginal examination the uterus had been found to be retroplaced, and a hard, nodular, immovable, and sensitive mass had been found to the right of and slightly posterior to the uterus. This mass had occupied the same position as the one found previously. The diagnosis had been malignant disease of the right ovary. An operation for its removal had been advised, and had been performed at St. Elizabeth's Hospital. Although the vagina had been somewhat contracted and rigid, it had been decided to remove the tumor by this route. The incision had been begun about an inch below the meatus urinarius, and had been extended down the anterior vaginal wall to the cervix. The flap had then been dissected from the bladder, as in Mackenrodt's operation for vagino-fixation. A transverse incision at the cervico-vesical junction had been made, and the bladder separated from the uterus by blunt dissection with the fingers. The peritoneum had been incised, and the fundus of the uterus had been seized with a pair of bullet forceps and drawn forward. The finger passed into the pelvic cavity had detected the nodular mass surrounded by adhesions, but the parts could not be easily made out. At this time the patient, who had borne the anaesthesia badly, had become rigid, making further progress for the time being impossible. After a little delay it had been decided that as the uterus and tubes were in a fibromatos condition they should be removed. This having been done, although the patient was still rigid, it was possible to reach the tumor, which had proved to be composed of phleboliths. Three large ones, each of the size of a cherry stone, had been detached, and as the tumor had been apparently benign in character, and in view of the difficulty with the anaesthetic, it had been deemed best to terminate the operation without further interference. The pelvic cavity had then been irrigated with hot saline solution, and the wound in the vaginal walls had been closed with a continuous catgut suture, no drainage being employed. A little iodiform gauze had been placed in the vagina and an antiseptic pad over the vulva. The patient had so far made a good recovery, and she had had no pain. Her pulse and temperature had become normal on the second day, and her urine had been passed voluntarily at the end of thirty-six hours. The gauze had been removed from the vagina on the second day, and had not been replaced. To-day, the fifth since the operation, the wound had apparently healed, and the patient moved easily from side to side and was free from pain.

Dr. Gouley said that he had seen these phleboliths removed, and he had suggested that the woman had had at some time an injury, which had caused thrombosis of the veins between the broad ligament and the rectum. A number of thrombi must have been formed, because the tumor had felt like a bag of buckshot. These were the largest phleboliths he had ever seen; they measured a centimetre in mean diameter. As was well known, phleboliths were developed from the calcareous infiltration of thrombi. They were very commonly found in old men with enlarged prostates, in the venous plexuses between the surrounding prostate and rectum. He had seen hundreds of them in this situation, but none so large as those in the case under discussion. The specimens were still encapsulated in the veins. Cases of sepsis after operations on the genital organs of women were probably not infrequently due to softening of such thrombi, such as originally occurred in this case. The finding of these phleboliths had decided against the malignancy of the tumor.

A New Intestinal Clamp.—Dr. W. S. McLaren presented a new instrument of this kind. He said that some months ago, feeling the need of a light clamp for preventing the escape of intestinal contents while an anastomosis was being made, he had devised this extemporaneous clamp. It could be made in a few minutes wherever a steel knitting needle could be procured. The knitting needle was simply broken in two pieces of about equal length, the parts laid parallel, and the broken ends united by a few figure-of-eight turns of stout silk. This silk formed the hinge, and a cork pushed upon its sharp ends was the catch. In use, either point might be thrust through the mesentery. The two points were then brought together until the proper amount of compression was secured, when the cork was pushed over its points, making the clamp secure. It was, of course, necessary to wrap the broken ends of the needles in a piece of gauze to prevent any possible injury from the sharp corners. This clamp, the speaker said, was light—a very desirable feature in an instrument of this sort; it could be quickly made and easily sterilized, and was perfectly competent. He had used it in several operations for intestinal obstruction and had never had any leakage. It had worked so satisfactorily that he

had had Mr. Ford make a clamp for him on the same general principles, but with a permanent hinge and lock. The advantage of this hinge was that it could be quickly adjusted and very thoroughly cleansed. At the time of an operation the two parts should be separated. The operator had then simply one straight needle to handle while piercing the mesentery. When this was in place the other part was hooked through its eye and brought down until it locked.

Resection of the Colon for Adeno-carcinoma.—Dr. W. S. McLaren presented a specimen of adeno carcinoma of the colon, and reported a case. (To be published.)
Dr. W. Evelyn Porter said that certainly those who operated on emergency cases must find this new clamp exceedingly useful. The result of the operation was also particularly satisfactory. In cases of resection, even of the large intestine, it seemed to him that the Murphy button was of the greatest aid. He recalled a recent case in which this button had been used in resecting about six inches of the splenic flexure of the colon. The button had come away within a few days, and there had been an uncomplicated recovery.

The President said that the clamp seemed to him very ingenious and satisfactory, yet he would utter a word of warning against any clamp that perforated the mesentery. The case of failure after intestinal anastomosis that he had seen had been due to the failure of union of the intestine at the mesentery. He had more than once seen a very slight injury of the mesentery result in serious gangrene of the intestine; therefore, if any clamp were to be used, one working on the principle of the ordinary clothespin, and not perforating the mesentery, seemed to him the better. Of course, if one were willing to perforate the mesentery, a piece of gauze or tape might be used with satisfaction. Some years ago he had devised a clamp which operated without perforating the mesentery, but after a while he had found that he could do just as well without it. If the intestine were stripped back far enough, and held properly by assistants, there would be no leakage.

In answer to a question from Dr. Robert T. Morris, the speaker said that in cases of gangrene of the bowel mentioned, the gangrene had been due to the interference with the blood-vessels.

Dr. Wigan said that he wished to congratulate Dr. McLaren both on the clamp and the operation. He had used the clamp experimentally on the lower animals, and had found no injury to the mesentery afterward. Last October, assisted by Dr. McLaren, he had done a double anastomosis on a dog, using the Murphy button and also the Mannsell method. The dog had been killed a week ago, and it had been found that the lumen of the gut had been maintained in both instances.

Dr. McLaren said that in the country competent assistants could not often be obtained, and therefore it became necessary to have something to control the intestine. This was the reason for using the clamp. In the case referred to, there had been enough facial matter to fill three bedpans when the bowels had moved. He had had the clamp made with a blunt point so that it would not injure the blood-vessels. He thought that by placing it some distance from the intestine, the vessels would be crowded aside and not injured by the clamp. One objection to the use of the Murphy button low down in the intestine was the extremely thick and often very short mesocolon. In a case like the one reported, he felt that the button could not have been used on account of the extremely low site of the trouble.

Report of Some Cases of Fibrous Ankylosis treated by Electrolysis.—Dr. Fred. Walker Gwyer read a paper with this title. (To be published.)

Dr. George Woolsey said that he had not applied the electricity personally in any of these cases, but had sent the patients to the reader of the paper, or had had them treated by the house staff of the hospital. The cases could be classed as: (1) cases of injury, (2) cases of disease, and (3) cases of stiffness following operation. In all these, benefit had resulted from the treatment, and in some cases it had been surprisingly rapid as well as marked. He recalled one or two cases of tubercular joint disease successfully treated in this way. Two cases had been cured by injections of iodoform emulsion, and the application of electricity had greatly relieved the pain and increased the motion of the joints without the pain attending passive motion. The larger number of cases in which good results had been obtained were those following injury. With one exception, these cases had done extremely well. This method of treatment, of course, came in competition with massage, passive motion, and even breaking up of adhesions under other. The last he had usually found rather unsatisfactory, because the adhesions generally re-formed after a time. Of course, massage and passive motion were valuable, but they were often not well applied. He felt that his own experience was sufficiently large to justify him in recommending this treatment very highly, in conjunction with other methods, or where other methods had failed.

Dr. Reginald H. Sayre said that he had had but a limited experience with the method. He had sent some old tubercular cases to Dr. Gwyer in the hope that the motion of these stiff joints might be improved. He did not feel that the effect in this class of cases had been great, although in a case of rheumatism he had seen it act very beneficially in relieving the pain and stiffness. From a theoretical standpoint he felt that the method of treatment should be beneficial, but why it should be more successful in rheumatic conditions than in stiffness of joints following tuberculosis he could not say. Galvanism should act upon the human tissues and produce electrolysis just as it did in the laboratory, and therefore one would expect that it would dissolve the adhesions.

Dr. C. G. Sproull said that he would like to refer to the effect of galvanism in treating a synovitis of the knee joint occurring in his own person. The synovitis had been the result of injury, and had occurred about seven weeks ago. The knee had been treated by elevation, massage, and the Martin bandage, which had been removed twice daily and massage treatment given, and afterward by plaster of Paris. At the end of one month the plaster had been removed, and on using the knee for about a week the synovitis had been nearly as bad as before. Seven days ago, Dr. Gwyer had begun treating him with galvanism. At this time the circumference over the patella had been seventeen inches on the affected side, as against fifteen inches and three quarters on the other patella. He had received four applications, with the result that there had been a marked diminution in the fluid and oedema, and a very great increase in the motion.

Dr. Gouley said he had noticed that the reader of the paper and several of the speakers had made use of the words "electricity," "galvanism," and "electrolysis," and he would like to know which of these three methods had been used on the cases reported.

Dr. Gwyer replied that electrolysis had been used.

Dr. Gouley said that two or three professors of electrical science had lately said that they were surprised that physicians were using some of the forms of electricity for the cure of certain diseases, for they could not conceive that ordinary electricity or galvanism could possibly have any effect except as a kind of gymnastics of the muscles, and that nothing short of electrolysis had any positive action. Electrolysis exerted a destructive action, as its name implied. Electrolysis applied to a surface was supposed by the reader of the paper in discussion to exert some mysterious selective effect on certain adhesions within a joint. This curious selective effect he could not understand. He would like to know whether there was any explanation of such a phenomenon as the selection and dissolving of these adhesions. He believed that he had been one of the first to use the electrolytic process in this country. He had employed it in a tumor of the thigh which had proved to be a sort of hygroma. In this case the electrolytic process had been so thorough that a large abscess had formed. This had been the experience of other surgeons. The electrolytic process had been
applied in cases of stricture of the urethra with the almost invariable result of causing a traumatic stricture. He had had under his observation several cases that had been reported as cured by electrolysis, and yet he had found a few months after the treatment that they had had traumatic strictures. In conclusion, he would ask whether the electrolytic process had any selective effect on these deep-seated processes.

Dr. L. W. Hotchkiss thought that the paper showed quite clearly that galvanism had no selective effect on old, well-organized adhesions, and that the author had found, as many others had done, that the best results had been obtained in the more recent cases. During the past few years he had had an opportunity of using electricity at the Roosevelt Dispensary. He had employed a weak galvanic current, although in a somewhat desultory and routine manner, and in connection with massage, active and passive motion in various painful joints, and in recent ankylosis. In almost all cases of Colles’s fracture, with stiff and painful joints, in which electricity had been used, the result had been satisfactory, but, inasmuch as douching and rubbing and motion of the joints had been used with the electricity, it was difficult to say in these cases how much the electrical current had really accomplished.

Dr. Gwyer said in reply to Dr. Gooley’s question, that on the removal of the positive electrode, after the employment of a heavy current, one would find evidence of a charring action of the current, whereas the skin under the negative electrode would show rather a vesicant action. He did not know that any physician or electrician could say positively what was the action of the current on the tissues beneath the skin. He believed, however, that the electrolytic action of the current was exerted most powerfully on newly formed fibrous tissue, and, by regulating the amount of current, its action could be quite closely confined to this tissue. The knowledge of professors of electricity was no doubt thorough as regarded their subject, but few of them were familiar with its clinical application. They furnished the electricity, and the physician or surgeon used it, learning its action by experience.

Dr. Gooley said that his question yet remained unanswered, and he did not believe it could be answered. He would challenge all those who practised electrolysis to go further. In point of fact, there was no selective affinity—at least, it would be very strange if there were. If electrolysis were employed consistently, it would result in the destruction of all the tissues in the locality treated. The reports of the cases of fractures, with more or less adhesions about the wrist joint, had particularly interested him, but he had never seen a case of Colles’s fracture in which, after a reasonable time, there had not been good motion. The tendency had been to extend the splints beyond the joints and keep them in that position for several weeks, and, of course, as a consequence there would be temporary stiffness. With the short splints there need never be any stiffness. If there should be any stiffness, the interrupted electrical current to whip up the muscles would undoubtedly be useful, and electrolysis would be unnecessary or perhaps harmful.

Dr. J. F. Eichmann said that he saw no reason why in recent cases just as good results could not be obtained by massage and passive motion. He had seen a good many cases of stiffness after fractures, and yet he had not found it necessary to resort to galvanism. In one case, in private practice, he had found stiffness after Colles’s fracture, but in this patient there had been a rheumatoid arthritis. He had used galvanism in several instances, but had not observed any benefit from it.

Dr. Parker Syme said that for a number of years he had also worked with fracture cases in the Roosevelt Dispensary, and had observed the effect of galvanism. Since leaving the dispensary he had used the other means without the galvanism, and his results in the same class of cases had seemed to him equally good. He had often employed active motion instead of passive motion. The cases reported in the paper seemed to indicate that the greatest improvement had occurred in just those cases where improvement was what was to be expected naturally at the stage at which the treatment was begun. He had used surface irritation about joints by the Faggin cautery with much satisfaction, and it was possibly the surface irritation produced by the current that had produced the benefit. While at Bellevue Hospital he had devised a splint made of perforated sheet lead, to be used in cases of Colles’s fracture, with the idea of avoiding undue immobilization of the joint.

Dr. Spruell said that the treatment had acted in his own case as a cautery, and it was probably by the stimulating action of the current on the circulation that the good effect had been produced.

Dr. Gwyer, in closing the discussion, said that he had been much pleased with the criticisms evoked by the paper. His reason for limiting his paper to histories of cases was that nothing was definitely known about the action of the electrical current beneath the skin, and the subject being so broad, he had preferred presenting his results rather than his theories, and would only say he believed that there was, first, dissolution of the newly formed fibrous tissue, and, secondly, a stimulating effect (possibly similar to that produced by the thermo-cautery), which increased the flow of blood to the part, and this hastened absorption of the dissolved adhesions. If every case of fracture were properly treated, there would probably be no need for electrolysis, or massage, or other after-treatment, but this was not the case.

OPHTHALMOLOGY.

BY CHARLES STEMDAN BULL, A.M., M.D.

(Continued from page 447.)

Formaldehyde as an Eye Lotion.—Gepner (Citrbl. f. prakt. Aug., June, 1894) recommends the employment of formaldehyde in solution of 1 to 2,000 or 1 to 1,000 for irrigating purposes during operations, and in all acute conjunctival diseases. It causes decided hyperemia of the conjunctiva and considerablesmarting, which, however, last but a short time in healthy eyes. In inflamed conjunctiva the secretion is markedly diminished.

An Apparatus for Transillumination of the Eyeball.—Birnbacher (Citrbl. f. prakt. Aug., August, 1894) has constructed an apparatus of this sort which consists of a cylindrical metallic chamber with appropriate handle, and containing an electrical lamp of four volts. The chamber is closed behind, but open in front, and into this opening is inserted, by means of a slide, a homogenous glass rod, which is not straight but is so curved at a distance of five millimetres from the beginning of the oblique section that the section surface runs parallel to the axis of the cylinder. By this curve it has become possible to hold the lamp-chamber out of the way of the observer while he is examining the illuminated eye.

The Action of the Oblique Muscles in Astigmatism.—Wilson (Arch. of Ophthal., xxiii, 3) draws the following conclusions from his observations: 1. Compensatory rotation of the eyeballs in astigmatism will be necessary in order to secure binocular single vision whenever the predominant diffusion lines of any object upon the retina of one eye and the normal or diffusion-line image in the other eye do not fall upon corresponding retinal points. 2. This lack of retinal correspondence or rotation of the image is a function of (a) the amount and character of the astigmatism; (b) the nature of the ametropia; (c) the nature of the object viewed; (d) the action of the ciliary muscle.

Is there Coexcitation of Homonymous Sections of the Visual Field such as Schiele has described?—Graevenouw (Arch. of Ophthal., xxiii, 3) draws the following conclusions from his experiments:

1. The fatigue curves, as shown in the plates and tables, do not run in any case with even an approach to the regularity that Schiele professes to have found; on the contrary, they cross one another in the most manifold way.

2. The statement of Schiele that “contraction of the outer borders of one sector of the visual field has no influence upon the outer borders of adjacent sectors nor of any other portion of the same visual field” could not be substantiated; on the contrary, it was found that almost always fatigue of one sector of the visual field is accompanied by changes in the outer borders of other sectors of the visual field of the same eye.

3. Schiele makes the statement: “Fatigue of the visual sphere, which is caused by taking the visual field of one eye, is communicated to those fibres of the second retina which end in it in such a manner that in every case only homonymous portions of both visual fields show contraction.” The previous experiments did not confirm this; for although in a series of cases the homonymous sector of the visual field of the second eye showed analogous changes in its outer boundaries to the fatigued one in the first eye, this was often not the case. Further, sectors of the second eye, which had not been directly fatigued, and which were not in the least homonymous to the fatigued sector, gave evidence of having been influenced.

The Primary Tumors of the Optic Nerve.—Braunschweig (Arch. für Ophthal., xxxix, 4) divides these tumors into various classes, according to the time at which exophthalmia begins: 1. Cases in which blindness comes on before the exophthalmia. 2. Cases in which, simultaneously with or shortly after the appearance of the exophthalmia, the vision begins to fail, and slowly but steadily grows worse until total blindness is reached. 3. Cases in which the vision does not begin to fail until long after the exophthalmia has become manifest and slowly grows worse. 4. Cases in which the vision is but little or not at all affected by the growth of the tumor. This is only observed in endothelial growths. The cause of the amblyopia and amaurosis is always due to an interruption in the conductibility of the fibres in the optic nerve itself, caused by pressure atrophy or by the infiltration of the nerve fibres with the morbid growth. The diagnostic symptoms are as follows: 1. Gradual painless course without signs of inflammation. 2. Early loss or rapid
diminution of the visual power. 3. Relatively normal motility of the eyeball. 4. A palpable or tangible tumor within the muscular cone back of the eyeball.

Myxosarcoma of the Optic Nerve.—Salzmann (Arch. für Ophthal., xxxix, 4) reports three cases of this nature. In all three cases the tumor was separated from the eyeball by a segment of normal nerve, but reached as far backward as the foramen opticum. The origin of the tumor seemed to be in the posterior portion of the orbital part of the nerve, and the general tendency of growth was forward. The growth of the tumor was due partly to an actual proliferation of tissue with the development and enlargement of the cells, and partly to increase in the amount of intercellular fluid. When unsuccessful extirpation has been done, some traces of the neoplasm have been left behind in the optic foramen. These tumors may be regarded as benign, and hence the eyeball should always be preserved intact in any operation undertaken for the removal of the tumor.

The Anatomy of the Congenital Crescent Downward and Inward.—Salzmann (Arch. für Ophthal., xxxix, 4) has found that in these cases there is an absence of all signs of distortion of the choroid and of the adjacent inner layers of the sclera. The deep cutting in of the choroid on the side toward the crescent is also absent, as well as the distortion of the nerve-fibre bundles on the side toward the crescent. Throughout the entire region of the crescent there is a doubling in the thickness of the retina, but with partial incomplete development of the two lamina.

The Influence of Closure of the Arteria Ophthalmica and the Carotid on the Organ of Vision.—Elsching (Arch. für Ophthal., xxxix, 4) gives the following results of his investigations: The gradual slow closure or thrombosis of the ophthalmic artery, internal carotid, or common carotid has no influence upon the circulation in the vessels of the orbit or retina. Sudden obstruction of the ophthalmic artery or carotid may cause temporary, fleeting disturbances of vision, but without anatomical lesions, since the intimate and extensive anastomoses between the branches of the ophthalmic artery and external carotid of both sides soon restore a normal circulation and blood pressure in the vessels.

The Relative Range of Fusion in Elevation and Depression of the Visual Plane.—Schmidt (Arch. für Ophthal., xxxix, 4) considers that the situation of the range or field of fusion is in elevation of the visual plane sometimes the same as in the horizontal or depressed visual plane; but it is generally so displaced that a somewhat greater power of divergence and a diminished power of convergence is present than in the depressed visual plane. The position of the field of fusion is dependent on the existing condition of equilibrium of the eyes. The positions of equilibrium in elevation and depression in various states of accommodation lie generally close inside and approximately about the same distance from the limits of divergence of the fields of fusion. Consequently, with increasing accommodation there results a proportional increasing insufficiency of convergence.

The field of fusion in elevation of the visual plane either remains of the same size, or becomes smaller at the expense of the power of convergence, as it is in depression of the visual plane.

The Significance of the Pitcher-cells of the Conjunctiva.—Green (Arch. für Ophthal., xl, 1) considers these cells as normal structures, which are always found in the normal conjunctiva of man and animals. In structure and function they are probably analogous to the pitcher-cells found in other parts of the animal body, as in the skin of certain fishes, in the mucous membrane of the frog’s bladder, in the small intestine of man. They are intended to produce mucus by a natural and physiological process.

Primary, Secondary, and Tertiary Retinal Images after Momentary Light Impressions.—Boscha (Arch. für Ophthal., xl, 1) draws the following conclusions from his observations:

1. The consecutive retinal images appear in the purest and simplest form with the shortest possible illumination of a circumscribed region of the retina, with exclusion of every other source of light.
2. Contrast effects also occur in the vicinity of the retinal image by illumination with the electric spark.
3. The perceptive processes are more distinct when by local retinal irritation a contrast irritation is produced in the surrounding zone.
4. The perception image in its simplest form has three phases: The primary image, which lasts longer than the illumination itself; the secondary image, which has the complementary color of the first, and is the more distinct the shorter the illumination is; the tertiary image, which has no definite color, and the duration of which increases with that of the illumination.
5. The third phase of the retinal image is distinguished by diminution of the sensitiveness for weak, objective light.
6. The after image of a long-continued, homogeneous illumination is a complex process, composed of the accumulation of a series of light impressions immediately following each other.

Observations on the Ocular Symptoms occurring in Syphilis of the Central Nervous System.—Uhthoff (Arch. für Ophthal., xl, 1) continues his observations on this subject in a second lengthy and interesting paper. He finds that in affections of the trigeminal in consequence of cerebral syphilis, as well as in the neuro-paralytic keratitis connected with them, the cause must be regarded as basal in origin. The optic channels of conduction are relatively more frequently affected than the motor and sensory nerves.

Siderosis Bulbi and the Relations between Siderotic and Hematogenous Pigmentation.—Von Klippel (Arch. für Ophthal., xl, 1) draws the following conclusions: 1. The iron reaction with potassium ferrocyanide and hydrochloric acid succeeds even in preparations which have been preserved for a long time in Müller’s fluid. 2. The Berlin-blue reaction gives the same results as Quincke’s with ammonium sulphate. 3. There is a real siderosis bulbi, arising either from the presence of a foreign body or from the blood. Siderosis is the deposit of ferric oxide in certain groups of cells in organic substances. 4. Hematogenous siderosis is completely independent of hematogenous pigment. 5. Siderosis appears especially in certain groups of cells, as the epithelium of the ciliary processes, the pars ciliaris retinae, the retina, and the epithelium of the lens capsule, and may be either xenogenous or hematogenous. True siderosis of the cornea has never been positively demonstrated. 6. Xenogenous siderosis results from the solution of the iron by the carbonic acid of the tissue, and its precipitation in the groups of cells the protoplasm of which shows an especial affinity for the iron. 7. Neither the greenish nor greenish-brown nor rusty discoloration of the iris and cornea point with certainty to the presence of a particle of iron in the eyeball. 8. The characteristic circle of brown spots under the lens capsule in the case of the presence of a foreign body is due to the deposit of iron in circumscribed patches of proliferating capsule epithelium. 9. When a particle of iron is present in the vitreous, extensive degeneration of the retina results. 10. After injection of blood into the vitreous, detachment of the retina may occur, with signs of general retinal degeneration. 11. If blood
be injected into the vitreous after puncture of the anterior chamber, the anterior capsule of the lens sometimes becomes ruptured.

The Sideroscope: An Instrument for demonstrating the Presence of Fragments of Iron and Steel in the Eye.—Asmus (Arch. für Ophthalm., xi, 1) draws the following conclusions from his employment of the above instrument: 1. It is probable that particles of iron or steel may be demonstrated to be present by the siberoscope in nearly all cases, either by the simple magnetic needle or the astatic needle. 2. The localization of these fragments is possible by examination of all the meridians. 3. Astatic needles are in general unsuited to the purpose of localization.

Examination of an Eye with Double Perforation due to Injuries from a Fret Saw.—Duffing (Arch. für Ophthalm., xi, 2) has drawn the following conclusions from his observations in this case: 1. The scleral staphyloma was formed from the perforation from within outward of all the ocular membranes in the equatorial region of the upper half of the globe, while staphylomata of this region are usually not traumatic, but are the result of an increase of tension at the point of weakest resistance. 2. Traumatic staphylomata of the upper half of the globe depend on a stretching and thinning of the scleral layer and surrounding scleral tissue; but in this case the staphyloma consisted of entirely new-formed tissue furnished by the sclera, and this tissue is not thinned, but as thick as the normal sclera. 3. The fibres of the newly-formed tissue run in the same direction as the fibres of the normal sclera, and pass so imperceptibly into the neighboring normal tissue that the ends of the perforation are not demonstrable.

Deposits of Rust in the Cornea.—Gruber (Arch. für Ophthalm., xi, 2) draws the following conclusions from his observations: 1. Particles of iron which have penetrated the cornea vary in their action according to their chemical properties. Metallic iron and ferric oxide must be regarded as irritating, while ferric oxide is indifferent. The ring of rust remaining after the extraction of a particle of iron, consisting merely of a hydrated ferric oxide, is indifferent and unirritating. 2. Even in cases of non-perforating injury from particles of iron, there often results a deposit of ferric oxide on the membrane of Descemet. 3. The deposit of rust outside the foreign particle follows very rapidly after the injury. 4. The corneal epithelium resists very strongly the entrance of the ferric oxide deposit, while the power of resistance of the corneal substance proper varies in different persons.

Purulent Metastatic Ophthalmia; its Ätiology and Prognosis.—A xenfeld (Arch. für Ophthalm., xi, 3) finds that the eye appears to be less favorably disposed to the reception of compact plugs in the vessels than to capillary embolism. He attributes the development of purulent intraocular inflammation to the presence of the Diplotocus lanceolatus, which, however, according to most observers, rarely leads to panophthalmitis. In the cases of meningitis due to the presence of pneumococcus, he considers it probable that the cocci developed from the optic papilla may communicate and mingle with the cocci developed in the intervascular space, but admits that in these cases there are probably two distinct inflammatory processes present. The greater frequency in the occurrence of metastatic ophthalmia over that of metastatic orbital cellulitis probably points to the prognostic significance of the finest capillaries in favoring the development of this inflammatory process. Bilateral metastatic ophthalmia is of greater prognostic significance than unilateral ophthalmia in reference to a fatal result.

Descemetitis.—Snellen (Ophthalm. Rec., August, 1894) concludes that descemetitis is really a disease sui generis, and that it is due to microbes growing in the anterior chamber, which, by their producing toxins, cause an irritation of the uveal tract.

The dots are at first situated on the cornea, afterward on the iris and lens, and may be also on the ciliary body. They contain in their early stages only microbes, but later these are intermixed with leucocytes.

Cellulitis following Mule's Operation.—Stephenson (Ophthal. Rec., September, 1894) reports a case of this nature, and thinks its occurrence may be explained by assuming the existence of a septic infection passing by the perforating veins of the sclera into the tissues of the orbit and there setting up inflammation. It is not impossible that septic changes were present prior to the operation, and that the altered nutrient and other conditions brought about by surgical interference roused into activity germs that had long lain dormant in the tissues. The alternative theory, that infection occurred during operation, must of course be carefully considered.

A Case of Probable Disease of the Lenticular Ganglion.—Taylor (Ophthalm. Rec., September, 1894) reports a case of obscure disease, which had been diagnosed as glaucoma. The eyeball was congested, the pupil dilated, the tension increased, and the vision misty. The patient was forty-nine years old, with a myopia of D. 18. There was a good deal of neuralgic pain in the eye and vicinity, and the eyeball was slightly protruded. Taylor thought that the rapid onset with the associated symptoms and the progress were opposed to the lesion being situated in the third-nerve nucleus or any part of it. Though observed for nearly two years, the affection remained unilateral, and the iris now reacts slowly to convergence. He did not believe it due to an affection of the intracranial ganglionic cells of the choroid, and therefore attributed the symptoms to an acute affection of the lenticular ganglion. In such a lesion, motor, sensory, and sympathetic fibres would be interfered with. The circular fibres of the iris would be paralyzed and the accommodation would be lost, while the dilating fibres which received innervation from other sympathetic sources would be partially paralyzed only. Hence the pupil would remain dilated and inactive to light and convergence for some time, and, if no reparation of tissue took place, perhaps permanently. He thinks that in this case there was an attack of orbital cellulitis which caused the congestion, proptosis, and apparent glaucoma, and at the same time involved and more or less wrecked the lenticular ganglion, so that as soon as the results of the cellulitis had cleared up the more permanent effects came into notice.

Motor Ocular Paralyses due to Lateral Pressure of the Skull.—Panas (Arch. d'ophtal., August, 1894) draws the following conclusions from his observations: 1. The majority of oculares paralyses met with in injuries of the skull are due to fractures of the base. 2. The absence of any sinking in of the bones of the vault does not exclude the existence of fissures at the base. 3. The nerves which are in most intimate connection with the bones, the sixth pair of cranial nerves, are most frequently paralyzed. 4. The pressure comes from the fracture itself or from extravasated blood within the skull. In the first case the paralysis is more or less immediate; in the second it may be postponed.

A Case of Myxoma of the Cornea.—Mitvalsky (Arch. d'ophtal., August, 1894) reports a case of this nature occurring in a woman, aged twenty-six years, dating from infancy. The tumor was a pure myxoma resembling a lobulated polypus, implanted by a slender pedicle at the centre of the cornea. It contained a number of cystic cavities. The cornea was flattened, a staphyloma having been removed some years previously, and thus the base, which gave rise to the tumor, was a mass of cicatricial tissue.

Researches into the Microbic Condition of the Conjunctiva in Persons affected with Ozaena, without Complication of the Lacrimal Passages.—Terson and Gabriéldés (Arch.
REPORTS ON THE PROGRESS OF MEDICINE.

It "battery" accompanied 1.

Strabotomy.—Landolt (Arch. d’ophthal., August, 1894) considers the advancement of the antagonistic muscle a much more valuable surgical procedure for the relief of squint than tenotomy of the squinting muscle. Even in cases of simple insufficiency of convergence or divergence, where tenotomy is admissible, the results of the latter are often unsatisfactory, because a considerable portion of the adducting or abducting power is lost. When the squint is excessive, tenotomy is often inconvenient on other grounds. In the operation of advancement, the excursions of the eye are always increased, without any loss in the power of the antagonist. Moreover, both convergence and divergence gain more by this operation than by tenotomy. Finally, the operation of advancement never causes any disfigurement. Tenotomy may be considered in cases of motor insufficiency, latent squint, or squint of a low degree, according to most modern ophthalmologists, but Landolt believes that in all three classes of cases advancement offers greater advantages. It has never in his hands caused an over-correction of the defect. It must, however, be generally done on both eyes.

Bony Tumors of the Orbital Region.—Mitvalsky (Arch. d’ophthal., October, 1894) considers that the clinical features of osteomata of the frontal sinus are sufficiently uniform, and consist chiefly in a bony elevation of the region of the sinus, accompanied by a bony loss in the neighboring orbital cavity and by exophthalmia. The pathological processes in the mucous membrane of the sinus consist in a chronic inflammation with secretion of pus or mucus-pus more or less abundant in quantity. This secretion is accompanied by the formation of mucous polypi. The mucous cysts do not remain in the same spot, but are dislodged by the growth of the osteoma. Such a cyst, displaced toward the brain, may cause death by purulent inflammation. An operation for the removal of an osteoma may be undertaken at any stage of its development so long as no pathological changes have occurred in the brain or its membranes.

Tuberculous Iritis.—Vignes (Réc. d’ophthal., April, 1894) draws the following conclusions: 1. Tuberculous iritis must be distinguished from other varieties of iritis. 2. This form of iritis is premonitory of the appearance of tuberculous nodules elsewhere. 3. Its invasion is insidious, slow, and with but little local reaction, but is accompanied by numerous posterior synechiae. 4. The absence of pathognomonic symptoms makes the diagnosis difficult. 5. The tendency to spontaneous healing of miliary tuberculosis of the iris depends upon the natural resistance of the iris tissue. The encapsulation of the tubercle and the rapid obliteration of its nutrient capillaries favor its isolation and the protection of the healthy tissues.

Monocular Polypia.—Landman (Annals of Ophthalm. and Otol., iii, 1) reports two cases of this affection due to traumaism. The patients did not notice the diplopia immediately after the accident, though it might have existed. In both cases there was convergent squint, in one case of both eyes, and monocular diplopia in each. Landman thinks the difficulty was in the visual centres, due to a haemorrhage and clot which was organized and finally absorbed. The centre was subdivided by this act, and it comprised two or more impressions from one image. The question is whether the physical continuity of a centre may be destroyed with or without destroying its psyche or physiological power. He thinks it possible to conceive of a haemorrhage forming a line of separation and barrier, preventing impulses from diffusing themselves, and one centre thus dividing itself into two or more. He thinks that unilateral diplopia may be the result of a lesion separating the visual centres within itself, and the peripheral impression being one, and the central two or more.

Description of a New Optometer for the Correction of Astigmatism by Distant Tests.—Welland (Annals of Ophthalm. and Otol., iii, 1) alleges the following advantages for his instrument: 1. The instrument is used for distant objects, thus avoiding the tendency to accommodation so often excited by an artificial punctum remotum. 2. The objects appear of the same size as the test lenses from the trial case in the usual position make them appear. 3. No tube is used that may embarrass the patient and excite his circulatory muscles. 4. It allows of the correction of astigmatism by the direct use of cylindrical glasses. 5. By using in connection with the highest plus and lowest minus spheres only negative cylinders, we are more likely to get the fullest correction for hypermetropia, and avoid an over-correction in myopia in cases where a mydriatic can not be employed.

A New Instrument for Testing Adduction, Abduction—Exophoria, and Esophoria.—Gould (Annals of Ophthalm. and Otol., iii, 1) has devised a “battery” or “pile” of prisms for this purpose. The prisms begin with one-degree lenses upon each side, and increase by integers to twenty degrees, so that with two-degree steps we may test all degrees of adduction or abduction from two degrees to forty degrees. The open central space permits the lenses to be brought close to the eyes without any interference with the patient’s nose. The larger handle below allows the first tests to be made with the lower-power prisms, likewise without the handle striking the nose. The lower-power prisms are placed below in order that in testing from lower powers to higher powers the breadth of the patient may not cloud the lenses to be used next in order. To test ad-duction, each battery is placed bases out; to test abduction, each is revolved so that the bases are in. To test exophoria and esophoria the same methods are pursued, the Maddox rod being first placed before one eye in the trial frames. Each battery is revolved at pleasure, being fixed by a pivot mechanism below and temporarily held in the position desired by clutches at the side.

The Conservative Treatment of Muscular Insufficiencies.—Heath (Annals of Ophthalm. and Otol., iii, 2) gives the following reasons for a moderately conservative treatment of these cases: 1. The eye muscles are variable in their strength from day to day. 2. Our diagnosis may be wrong. A coincidence may be mistaken for cause and effect, symptoms due to some other cause being attributed to the insufficiency discovered. 3. The difficulty in deciding which is the cause and which the effect in some cases of nervous prostration with insufficiency of one or more eye muscles. 4. Some patients are neurotic by birth and can never be cured. Palliation is all they can ever expect, and radical treatment becomes hardly justifiable. 5. We should first thoroughly understand the effect of refractive errors and their correction. As errors of refraction frequently cause muscular insufficiencies, correction of the former will often relieve symp-toms due to the latter. 6. Regulating the effect of an operation is difficult if not impossible. It may be too much, too little, or none at all. 7. Results reported by operators are often due to other things than the operation. 8. Some cases show weakness of all the muscles. 9. Simple measures relieve many cases.

The Treatment of Heterophoria.—Dunne (Annals of Ophthalm. and Otol., iii, 3) believes that there is no single cure—all for any muscular anomaly. Some cases yield to training of the
muskies, some to correction of the refractive error, some to
tenotony, and some are incurrigible. We must first ascertain
the nature and cause of the underlying pathological condition,
and then apply the method of treatment that is adapted to the
state found. We must first find out what the exophoria or hy-
perphoria means; whether it is spasm or pariesis, accommoda-
tive strain or anatomical conditions, and then apply the proper
remedy.

A New Ophthalmoscope.—Skeel (N. Y. Eye and Ear Inf.
Rep., ii, 1) has devised an instrument in which the lenses are
arranged as in the Loring ophthalmoscope. The primary disc
is mounted on a short pinion, which also carries a pulley. The
secondary disc turns loosely on this pinion. A endless chain
runs over this pulley and extends downward through the hollow
handle to another pulley carried within it at its lower end. A
sliding piece extends through a slot in the handle and is at-
tached to the chain. This sliding piece is actuated by the
thumb as the instrument is held in the hand. When it is mid-
way in the slot the free aperture is in front of the eye.

By moving the sliding piece upward the chain running over
the pulley causes the disc to revolve and the successive concave
lenses are brought to the aperture. By moving it downward,
the successive convex lenses are moved in the same manner.

Soc., 1894) has devised a small perimeter which consists of a metal
ring 0.25 millimetre in diameter, with brass pins projecting
from it at intervals of thirty degrees. At right angles to this
ring is a half ring with projecting spokes at intervals of ten
degrees to mark the position of the string used as the radius on
the meridian. Projecting toward the centre of this half ring is
a post with an eyepiece in its end through which passes a piece
of suture silk. These three parts, with an ivory handle, complete
the instrument. When in use one eye of both patient and ob-
server should be covered. The pupil of the patient’s eye, the
side of the metal post of the instrument, and the pupil of the
observer’s eye should be in line. The patient should be asked to
open the eye widely just before the metal ring is brought in con-
tact with the lids. It is more convenient, and sometimes neces-
sary, on account of projecting brows, to tip the patient’s head
back a little, and this, of course, increases the upper part of the
field. The length of the swinging radius can be varied with
the length of the surgeon’s arm. Bits of paper can be threaded
on the string and used as markers.

Recent Experiences in the Treatment of Detached Ret-
ina.—Bull (Trans. Amer. Ophthal. Soc., 1894) draws the follow-
ing conclusions from his experience:

1. The science and practice of opthalmology have as yet
discovered no better means for dealing with detachment of
the retina than the old methods which have been advised and
carried out for so many years—viz., rest on the back in bed,
atropeine, a bandage, and the internal administration of some
drug which may induce absorption of the subretinal fluid, 2.
The continual use of pilocarpine, either hypoderminically or
by the mouth, may cause great prostration, even in cases in which
it is apparently well borne; and the desired effect may be
sometimes produced by small doses of sodium bicarbonate or
potassium iodide largely diluted with water. 3. In all recent
cases puncture of the sclera subconjunctivally may do good
temporarily by letting out the subretinal fluid and allowing the
retina to collapse, thus producing some improvement in the
vision; but the apparent improvement is generally transient,
and when membranous bands exist in the vitreous no improve-
ment can be expected from simple puncture. 4. Division of
fixed membranous opacities in the vitreous causes but little re-
action, and may do positive good, even without division of the
detached retina, as it reduces the danger of extension of the
detachment. It is positively contraindicated in cases where
the vitreous opacity is vascularized, as it would certainly induce
free haemorrhage into the vitreous. It should never be done
when there is an irritated or inflamed condition. 5. Division
of the detached retina may always be done in a quiet eye and
causes little or no reaction. If membranous bands are present
in the vitreous, these should always be divided at the same time.
6. In most cases all these operative procedures produce but tem-
porary improvement, and in many cases no effect whatever is
obtained. 7. There seems no good reason for further indorsement
of the method advocated by Schon, but every reason for rejecting it from the domain of opthalmic surgery.

A Refractometer for Skiascopy.—Lambert (Trans. Amer.
Ophthal. Soc., 1894) has devised an instrument which consists of
two superimposed discs, one of which contains nine convex lenses
ranging from + D. 1 to + D. 9, and ten concave lenses from
—D. 1 to —D. 10. The other disc contains 0.25, 0.50, 0.75, and
D. 10, convex and concave. By means of a gear movement
operated by a tube and rod, the latter working within
the former, both discs can be revolved either independently
or together with one hand, thus enabling the examiner to
rapidly bring the various lenses in front of the eyepiece with-
out changing his position during the examination. On the re-
verse side of the instrument is an arm carrying the eyepiece,
which arm can be swung to either side of the disc, thus adapt-
ing the eyepiece to either right or left eye. The arm supports
in front a graduated cell, in which a cylindrical lens can be
placed at any desired axis, or a slide containing six cylindrical
lenses of different foci, which are varied by raising or lowering
the slide, while the desired axis is obtained by rotating the cell,
and is indicated by a pointer on the scale. In using the instru-
ment in cases of astigmatism, first estimate the refraction of the
two principal meridians, employing only the spherical lenses;
then, placing the cylinder thus indicated in the cell at the proper
axis, repeat the test to insure accuracy.

New Inventions, etc.

AN IMPROVED DEVICE FOR CORRECTING CERTAIN
DEFORMITIES OF THE NOSE.

By F. E. Hopkins, M. D.

To correct deformity of the nose whose supporting frame-
work has been destroyed by accident or disease, one must make
use of some mechanical contrivance which shall serve as a sub-
stitute for the missing parts. The great problem has been to
devise a support of sufficient firmness to keep the soft parts in
position and which at the same time should be in form and ma-
terial so little irritating that it might be permanently retained.

To M. Létiévant* belongs the credit of first successfully
using a metallic framework for this purpose. He employed
aluminum as the material for the supporting bridge, and re-
ported his case at the Medical Congress in Paris in 1878. At
his suggestion in 1885, M. Claude Martin, who had done a great
amount of work in correcting deformities about the face, con-
structed a framework of platinum which by its form and ma-
terial promised firmer support. M. Létiévant made use of this in
August of that year with very gratifying results. Modifications
of this have been used in this country by Dr. H. F. Weir and
others.

While this leaves nothing to be desired so far as restoration

of the form of the nose is concerned, there is yet too great a liability to displacement, either from electrical contraction or by traumatism. To overcome this difficulty I desire to present the improvement shown in the accompanying cut. This form is the result of suggestions from the members of the throat staff at the Manhattan Hospital, and in the single case in which I have used it it gave admirable results. It is cut from a single sheet of platinum a fifteenth of an inch in thickness, and then molded to fit the individual case. The improvement consists in the greater breadth of the bridge allowing of molding over the nasal bones, and thus preventing lateral displacement and adding greatly to its stability. A V-shaped piece is cut from the centre of the upper end, which reduces width, allows of more ready molding, and relieves the thin skin over the nasal bones from pressure. Oval perforations are made in the bridge, which again reduce its weight, and the uniting of the tissues through these openings adds materially to its stability. The supporting arms are made much broader and thinner than in the original, that they may hold the arch in position with the least possible irritation from pressure. These arms are pointed at the ends, and when set into the openings drilled in the superior maxillary the bridge is certainly very firmly fixed in position. The arms are to be made longer than is absolutely necessary, and cut of suitable length for the individual case at the time of operation. The accompanying cut is full size. The perforations should be made larger than represented.

By doing a Roux's operation one secures ample room to place the bridge properly, and it is retained in position with surprisingly little irritation. The fact that this splint is made entirely of one piece of metal greatly reduces its cost—an item of importance to many patients. This platinum bridge was made for me by E. B. Meyrowitz, to whom I am indebted for giving shape to my ideas.

**Miscellany.**

A Case of Sclerema Neonatorum ending in Recovery

—in the *Lancet* for May 4th there is a report of a case by Dr. Archibald E. Garrod, of London, who says that sclerema neonatorum is so rare a disease, and so seldom ends in recovery, that he thinks it would be of great interest to record the following case, as in the present incomplete state of our knowledge of this and allied conditions the period has not yet arrived when such records are superfluous:

The patient, a male infant aged five weeks, was brought to the out-patient department of the Hospital for Sick Children at Great Ormond Street on November 5, 1894. The mother, a healthy looking woman, stated that this was her third child, Of the other two the elder was strong and well, but the second died in consequence of a fall at the time of its birth. The last pregnancy was preceded by a miscarriage at the third month, The father was said to be healthy. The family occupies three rooms on a first floor and no history of privation was obtained, The infant was born at full term, the head presented, and there was no particular difficulty at the birth except that the hemorrhage was somewhat excessive. He was a well-nourished and, except in one respect, a healthy child. There was not, and had not been, any rash upon the buttocks or elbows. The child was being nursed by his mother, who had an abundant supply of milk, which he took regularly and well. The back of the infant presented a remarkable induration, which extended, like a kind of carapace, over almost the entire dorsal aspect of the body, involving the deltoid regions and upper arms, the buttocks, and the thighs down to and including the popliteal spaces. The skin of the face, of the front of the trunk, and of the limbs was perfectly soft and natural. The edges of the indurated area were sharply defined, irregular, and mottled, and there was nowhere any tendency for the hardened parts to merge into the healthy parts. The skin over the affected parts was stretched, but not shiny, and in places exhibited a pink mottling; it could not be pinched up between the fingers; pressure produced no pitting, but merely rendered the surface pale for a time. The distribution of the induration was remarkably symmetrical. The legs could not be fully extended either at the hips or knees, and when extension was attempted the skin in the popliteal spaces became very tense and shiny. There was no swelling, edematous or other, of the hands or feet. The child was good-tempered, and the examination did not appear to cause it any pain or discomfort. There were no signs of any disease of the heart, lungs, or other viscera, and there was no intestinal disturbance. The urine was not examined. It was stated that the induration upon the buttocks was noticed immediately after birth, and the places were at first of a deep pink color. During the first nine days of life the hardness spread down the thighs, but as far as could be ascertained the extension to the back and arms only took place during the fifth week, just before the infant was brought to the hospital, by which time the color of the affected parts had become much paler than formerly. No history of any surface exposure to cold air or water could be obtained. Inunction of a drachm of cod-liver oil night and morning was prescribed. On November 12th, a week later, the induration in the dorsal and lumbar regions was rather less marked, but there was no noticeable change in other parts, except that the redness had practically disappeared. The general health continued good, the infant sleeping and taking his food well. There was no coldness of the skin or extremities, and the temperature taken in the rectum was 98° F. On this date inunction of blue ointment was ordered in place of the cod-liver oil. By November 19th there was decided improvement in the local condition. The skin of the back, although it appeared stiffer than that of the normal parts, no longer exhibited marked induration; the hardness in the deltoid regions had disappeared, but a small patch remained upon each upper arm. The hardness of the buttocks and backs of the thighs—i.e., of the parts first affected—was as distinct as ever, but had somewhat diminished in extent, and the hide-bound condition in the popliteal spaces was less marked. It was a noteworthy fact that as the induration cleared up it did not merely shrink at its borders, but isolated patches were left which had become detached from the main area. Moreover, no pitting could be elicited in the regions in which the affection was clearing up. On November 26th further improvement was evident. A very small patch of induration was noticed in the left parotid region, which had probably been previously overlooked. On November 29th the rectal temperature was 95°, and the induration had still further diminished in extent. On December 13th there were still isolated patches upon the upper arms and extensive induration over the buttocks. On this date the inunction of mucronial ointment was stopped, and that of cod-liver oil was ordered to be resumed. On January 31, 1895, there was only a small patch of induration upon the outer surface of each thigh and the child could extend its legs well.
The arms and back were entirely free. By March 14th the induration had completely disappeared; there was a slight cough but no abnormal signs were detected in the chest. The infant was good-tempered, well nourished, and slept and took the breast well. On April 18th the child weighed fifteen pounds and three quarters. The temperature in the rectum was 99-4°.

From the typical cases of selerema neonatorum, upon which the descriptions contained in the text-books are mainly based, says the author, this case presents certain well-marked differences, which, after all, are differences of degree rather than of kind, and which may be briefly summed up as follows: 1. The child, instead of being weakly at birth, was, with the exception of the local condition, in excellent health; and he had not suffered at any period of his brief existence from any pulmonary or intestinal disorder. 2. The temperature as taken in the rectum was at no time exceptionally low, whereas in severe cases the depression of temperature is one of the most conspicuous phenomena of the disease. The rectal temperature of 98-2° in the earlier stages probably indicated some depression, for it is stated that in young infants the temperature is as a rule over 99°, and on later dates the temperature was always somewhat higher in this case. 3. The induration after spreading in the earliest weeks of life became arrested, and instead of succumbing to the disease the patient made a steady and complete recovery. Now the only recognized condition with which selerema is apt to be confounded is the oedema sometimes observed in newly born infants. There is no doubt that these two phenomena have frequently been confounded, and such confusion permeated the earlier literature of the subject until Parrot clearly distinguished between them, pointing out that Andry and other French authors had applied Underwood's name of selerema to a quite different condition from that which he intended to designate. Those who are interested in this question, says Dr. Garrod, will find the differences between selerema and oedema neonatorum clearly set out in Hencbo's work on the diseases of children, and in a paper by Dr. Ballantyne. In their general condition infants which are the subjects of selerema and of oedema are apt to resemble each other somewhat closely, but the integuments of oedematous infants usually pit on pressure, although when there is great tension of fluid this character may be to a great extent wanting. Again, whereas oedema tends to begin upon the dorsal aspect of the body and legs, and thence to spread to the remainder of the surface, oedema is apt to appear in the hands and feet, and at an early period involves the abdominal walls and the scrotum or the labia. The author does not think that this case was one of oedema, for the following reasons: 1. There was no evidence of syphilitic taint in the child, and the history of a miscarriage preceding the pregnancy hardly suffices as evidence of this disease. There was no evidence of crysipelaon inflammation, of visceral lesions, or of any recognized cause of oedema. 2. The distribution of the hardness and the manner in which it cleared up, leaving isolated patches which persisted for a long time, seemed strongly opposed to the diagnosis of oedema. 3. The absence of pitting on pressure, even in parts in which the induration was disappearing and the tension could no longer be excessive, seems incompatible with such a diagnosis. Evidently, says the author, the case is one of a group tending to recovery, all more or less closely resembling each other, and, while differing in certain respects from the typical examples of selerema, exhibiting still more conspicuous differences from the oedema of the newborn as it ordinarily presents itself.

The Treatment of the Diseases of the Heart.—In the May number of the *Edinburgh Medical Journal* there is an interesting article on this subject by Dr. Byrom Bramwell in which he

suns up his personal experience as to the value of individual remedies which he has found most useful in the treatment of cardiac cases.

In many forms of cardiac disease, he says, rest is the most important means of treatment at our command. It is indicated in the following affections: Acute endocarditis; myocardial degenerations of all forms (fatty and fibroid); all cases in which there is reason to suspect myocarditis, whether acute, subacute, or chronic; pulmonary lesions with an engorged condition of the right heart; valvular lesions with decided breakdown of compensation; cases of angina pectoris in which there is reason to suspect organic disease; aneurysms of the thoracic aorta and large blood-vessels; and all severe cases of senile degeneration of the heart. Exercise is a very valuable means of treatment in many cardiac conditions, more particularly in neurotic affections, fatty infiltration, many gouty conditions in which there are no marked degenerative changes and arterial lesions, many valvular lesions, so long as the myocardium is fairly healthy, some dilated conditions of the heart in which the dilatation is associated with fatty infiltration or the result of such conditions at excessive beer drinking, and in which it is not associated with any marked degree of myocardial degeneration. In many cases of aortic and mitral disease, in the less severe forms of senile heart, and in the slighter forms of myocardial degeneration, judiciously regulated and moderate walking is invaluable, so long as the compensation is well maintained. By muscular exercise, says the author, we are enabled to promote the condition of the general health and of the cardiac health, to hasten the circulation through the peripheral organs and through the heart itself, and to prevent stasis and engorgement with all their disastrous results. So long as exercise, says the author, does not produce any untoward symptoms, it should be allowed and encouraged. Oertel's plan of treatment is chiefly used, he thinks, in cases of fatty infiltration, fatty and gouty conditions not associated with atheroma and without any marked degree of high pressure in the peripheral system of vessels. The author has had no direct personal experience with Schott's method, but from what he has learned from the experience of some patients he is disposed to think that it is chiefly valuable in the same group of cases and in cases of valvular lesions in which the cardiac muscle is reasonably sound. Dr. Bramwell says that he attaches the greatest importance to sustaining the mental tone of the patient. In many cases of cardiac diseases there is, he says, no tonic which is more efficacious than a favorable opinion confidently expressed. It is especially valuable in neurotic cases and in all forms of functional disease, and in the less severe forms of valvular lesion in which the valvular defects are well compensated for or in which the organic changes in the heart are associated with a nervous and irritable condition.

With regard to the employment of drugs, Dr. Bramwell recommends the following: 1. Iron is an invaluable remedy in those forms of cardiac disease in which there is a deficiency of hemoglobin. The most efficacious form is Robertson's Bland's capsules. 2. Arsenic is a valuable remedy. It is especially useful in cases of myocardial degeneration and in neurotic cases; it is also useful in many cases of angina pectoris. In many cases of valvular disease in which there has been any decided breakdown of compensation, particularly in cases of aortic regurgitation, it is a most valuable tonic. 3. Strychnine is one of the most valuable cardiac remedies which we possess for the purpose of producing both a sustained tonic effect and more active stimulation. Dr. Bramwell has found it very valuable in cases of valvular disease before there has been a decided breakdown of compensation, and during a temporary breakdown in which there are bronchial or other pulmonary complications, especially
when given subcutaneously in frequently repeated doses, with or without inhalations of oxygen. 4. Digitalis is a cardiac tonic which the author uses when symptoms indicating failing compensation are developed, for the purpose of producing immediate and temporary effects, tiding the patient over acute complications, also with the object of permanently sustaining the cardiac power and preventing further breakdowns of compensation. It is most useful in mitral lesions, especially in mitral regurgitation with dropsy, irregular pulse, scanty urine, etc. It should be given more cautiously and for shorter periods of time in cases of aortic regurgitation, and in such cases it can not be expected to produce such satisfactory results as in cases of mitral regurgitation.

Dr. Bramwell thinks that in some cases the employment of digitalis is attended with risk in fatty conditions of the cardiac muscle. He has seen one case of fatty degeneration in which rupture occurred during a course of digitalis, and he was inclined to think that the rupture was the result of the administration of this drug. He rarely gives it in chlorotic cases or where there is fatty degeneration due to disease of the coronary arteries; but he has found it of great use in cases where the grave cardiac symptoms seemed to be the result of a degenerated condition of the myocardium and in which the degeneration was the result of chronic myocarthritis or fibroid degeneration. Where the pulse tension is high, the author usually prescribes strophanthin in preference to digitalis. Under such circumstances, if digitalis is given, it should be combined with potassium iodide, sodium salicylate, or some remedy, such as nitroglycerin, which reduces the blood pressure. Dr. Bramwell always gives digitalis in the form of tincture or infusion. He never uses digitaline granules; he has seen, he says, decided poisonous symptoms produced as a result of the administration of Nativelle's granules.

5. Strophanthin is of great value in those cases in which it is desirable to produce a rapid tonic and stimulating effect. In such cases the author often combines it with subcutaneous injections of strychnine, and, in many cases in which there are grave pulmonary and bronchial complications, with inhalations of oxygen. Strophanthin is useful also in some cases in which digitalis, owing, perhaps, to some idiosyncrasy of the patient, disagrees. It is preferable also in cases where the peripheral arterial pressure is increased.

6. Alcoholic, amnioniacal, and ethereal stimulants are of great use for the purpose of relieving urgent symptoms and warding off asystole. Where there is vomiting, brandy and champagne are the most useful. Many persons, says Dr. Bramwell, who are suffering from chronic cardiac disease, who have all their lives been accustomed to the use of alcohol, are, in his experience, the better for a strictly moderate amount of alcoholic stimulant; in many cases of this kind it seems to help digestion; as a rule he gives whisky, well diluted, with meals. In functional and neuritic cases burgundy is often a useful form of wine.

7. Oxygen inhalations are of the greatest use in many very urgent conditions, especially where there is bronchitis, pneumonia, or pulmonary apoplexy. 8. Potassium iodide is an invaluable remedy in aneurysm and in many cases of angina pectoris. In combination with digitalis it is a most important remedy in some of the so-called cases of senile heart. It has also appeared to be useful where there is chronic myocarthritis or fibroid degeneration. In some cases in which cardiac lesions or symptoms were associated with symptoms of tertiary syphilis, potassium iodide has seemed to exert a beneficial effect upon the cardiac condition.

9. Sodium salicylate is another remedy from which the author has seen the greatest benefit result in gouty cases associated with cardiac symptoms. 10. Nitroglycerin and nitrite of amyl are the remedies which he uses for the purpose of producing a rapid lowering of the blood pressure. He thinks they are more reliable and safer drugs than nitrite of sodium. 11. Menthol, given in combination with aromatic spirit of ammonia and spirit of chloroform, is a most useful remedy in many cases of flatulent distention of the stomach—a condition which is often the cause of cardiac embarrassment and sometimes of sudden, alarming, and even fatal nocturnal dyspnea, with or without angina pectoris. A sixth or a quarter of a grain of solid menthol dissolved in half a dram of spirit of ammonia and half a dram of spirit of chloroform is the usual dose. 12. Purgatives are useful in many cardiac affections, especially in mitral cases attended with dropsy, and in cases in which the right side of the heart is overstressed and embarrassed, and the organs and tissues are engorged and water-logged.

In the mechanical removal of dropping effusions, says Dr. Bramwell, beneficial effects may be obtained by frequently repeated tapings in some cases of ascites due to organic cardiac disease, resulting hepatic cirrhosis, and portal engorgement. In cases of hydrothorax the results have, as a rule, been merely temporary and often unsatisfactory. He rarely resorts to puncturing the legs or the scrotum until other measures have failed to remove or lessen the oedema; consequently, in his experience, draining the subcutaneous tissues has rarely been attended with any marked or lasting benefit. Massage, he thinks, is a more useful remedy than tapping in many cases of subcutaneous dropsy; it aids the venous and lymphatic return, and quickens the circulation in the muscular and peripheral tissues of the body. It is also of great use in many cases in which, owing to the nature of the lesion, ordinary muscular exercise is contraindicated. Venesection is undoubtedly, he says, valuable in many cases in which the right heart is greatly distended and engorged, and it is particularly useful where the engorgement depends upon temporary lung complications superadded to mitral disease. Dry cupping is very useful for the relief of congestion of the lungs and other pulmonary and kidney complications.

With regard to the soporifics, says Dr. Bramwell, the most useful are chloralalimide, paraldehyde, and morphone. In cardiac cases sulphonal is much less certain in its action than chloralalimide, and in grave cardiac affections he has almost entirely given up the use of chloral hydrate, on account of the marked depression which it is apt to produce. Paraldehyde is especially useful in those cases where there is bronchitis, and in which morphone is contraindicated. After the breakdown of compensation and in the ultimate restlessness in cardiac cases, small and frequently repeated doses of morphone are often invaluable. The author has seen a marked benefit, even in cases where there was albumin in the urine, result from the administration of the drug, and he thinks that, on the whole, it is the most reliable sedative and soporific. It is an invaluable remedy in some cases of angina pectoris where nitrite of amyl fails to give relief or iscontraindicated; for example, where the blood pressure is low and where there is free arterial regurgitation. Morphone should never be given where there is oedema of the lungs or much bronchial secretion, for disastrous results have followed its administration under those circumstances.

The Therapeutic Uses of Guaiacol.—In the Pressa medica for April 20th there is an article on this subject in which the writer says that, although the therapeutic history of guaiacol has been known for the past few years, yet the only clinical observations on which any reliance can be placed with regard to its rational employment are of quite recent date. Formerly the guaiacol used was extracted from various kinds of creosote, impure products which were more or less charged with phenol, and consequently likely to give rise to accidents. Since 1893 we have possessed a pure product, perfectly definite, obtained
by synthesis by M. Béhal and M. Choay. It is the synthetic crystallized guaiacol which should replace the liquid guaiacols in the materia medica. It is the same, moreover, which was used during the present year by M. Linossier, M. Lannois, M. Guinard, and others in experiments, on the results of which we can rely to illustrate the therapeutic value of guaiacol for external and internal use.

With regard to the internal use of guaiacol, says the writer, it is generally well borne by the stomach owing to its local anesthetic action. It may be given by the mouth or hypodermically. When given by the mouth, the dose is from 1/6 grain to eight grains during the twenty-four hours in pills containing from 0/8 to 1/6 grain, in capsules containing the same quantity of guaiacol in an oily solution, or in alcoholic solutions, as, for example, the following: 1. Guaiacol, a hundred and fifty grains; rum, four hundred and fifty grains; distilled water, six ounces and a half. From eight to ten teaspoonfuls of this may be taken every day in milk or water. 2. Guaiacol, a hundred and fifty grains; vina de Bagnols, thirty-three ounces. From one to three dessertspoonfuls may be taken during the day.

When administered hypodermically, smaller doses are used; from 1/6 to four grains of guaiacol, dissolved in perfectly sterilized and neutral olive oil. A one-to-five solution is generally used, but equal parts may be employed. Guaiacol may be used in the following affections: 1. Pulmonary phthisis. It seems to be especially indicated in cases where the progress of the phthisis is sluggish, succeeding the period of softening with abundant expectoration. It should be handled prudently in erethic phthisis with a tendency to congestion and haemoptysis, and in tuberculosis in the beginning. The drug should be given, according to the condition of the digestive canal, by the mouth or hypodermically. The hypodermic injections of Weill and of Diemanntherber are preferred in the beginning by certain clinicians. Weill employed the following formula: Crystalized guaiacol, seventy-five grains; sterilized oil, 3-25 ounces. From two to three syringlefuls of this solution may be injected every day. 2. Chronic bronchitis, dilatation of the bronchi, fistula bronchitis, and pulmonary gangrene. In three cases of pulmonary gangrene Weill obtained very good results with hypodermic injections of guaiacol. The solution should be more concentrated than that used in phthisis; for instance, fifteen grains of guaiacol and a hundred and fifty grains of sterilized oil. In pulmonary gangrene, according to M. Lop, from one to four syringefuls may be injected every day. The same procedure and the same doses have been successfully tried in fistula bronchitis and in dilatation of the bronchi with phaenecly of the mucous membrane. In chronic bronchitis and in dilatation of the bronchi Grainger Stewart recommends guaiacol not only in hypodermic injections, but in intralaryngeal injections. He employed the following solution: Crystalized guaiacol, two parts; menthol, ten parts; sterilized olive oil, eighty-eight parts. Sixty grains of this were injected into the larynx twice a day. M. Naught also employed this method in fistula bronchitis with good results. Moreover, says the writer, all laryngologists at the present day use guaiacol for direct injections into the larynx and the trachea. 3. Purulent pleurisy. In this affection Robertson employed injections of guaiacol with very good results. He found that they were efficacious in diminishing the purulent secretion after empyema.

In the external use of guaiacol, says the writer, painting has become a common practice, and it is as important as the hypodermic injections or its administration by the mouth. It has been used pure or with equal parts of sterilized olive oil or glycerin. For the first painting thirty grains of this oil solution should not be exceeded, as stronger doses have occasionally provoked symptoms of agitation and collapse. The solution should be applied over a rather large surface, about 0/20 centimetre square. The preferred regions may be the forearms or the calf of the leg. Guaiacol has also been employed in combination with tincture of iodine and vaseline. Painting with this drug has been used in the following affections: 1. Tuberculosis. In this disease the paintings seem to have a powerful antipyretic action. In miliary tuberculosis and in the acute attacks that occur during the course of chronic tuberculosis, according to Bard, Courmont, and Boix, guaiacol gives the most remarkable results. Boix reported several cases where not only small doses resulted in rapid and intense effects on the fever and on the general condition, but the effects were apparently lasting and definitive. In several cases there were bacilli in the sputum. The drug should not be used in the treatment of very feeble persons in the last stage; moreover, it has no action on the hectic fever of this period. 2. Typhoid fever. Montagnon employed in this disease paintings with guaiacol over the inguinal region when the temperature was high, and he was able to combat the hyperthermia in twenty patients. Eight grains were used at a time, and not more than thirty grains during the day. With repeated paintings Moisy was able to maintain an almost normal temperature, and he noticed that the antithermic action of the drug seemed to increase. Cheron, however, pointed out the dangers that might follow a too prolonged use of the drug, owing to the insufficient renal elimination of guaiacol. Montagnon recommends the use of guaiacol especially in cases where the cold bath is contraindicated. Desplats also obtained very good results in typhoid fever with guaiacol. 3. Pleurisy. In this affection Miron Sigaléa painted the entire affected side twice a day with the following mixture: Guaiacol, forty-five grains; glycerin and tincture of iodine, each, three hundred grains. He has also seen this treatment succeed in recurring effusions after a first thoracoeentesis. In these cases the guaiacol appeared to have a diuretic effect, which was also observed in a case of scarlatinous nephritis with anasarca and anuria. Desplats also found this diuretic action in typhoid fever and in typhus. 4. Infectious pyemia. In influenza, pneumonia, rheumatism, etc., painting with guaiacol has an ordinary antipyretic action. In intermittent fever Kolos moderated the attacks in the beginning by injecting a mixture of guaiacol and lanolin over the spleen. In erysipelas of the face the paintings, according to Bard, may diminish the intensity and gravity of the affection. In all affections where the renal elimination may be insufficient the administration of guaiacol should be cautiously made and its action carefully watched. 5. Pultaceous angina and amygdalitis. According to Darboue, Raymond, Rhodes, and others, pharyngeal paintings give very good results in combating not only the fever, but the pain. The glycerin solution is preferable to the oil solution, and, for an adult, the two ingredients are prescribed in equal parts. For children, however, the dose should be weaker, one part of guaiacol and three of glycerin, and its action closely watched. The first burning is sharp and the taste rather disagreeable, but the relief is rapid. The difficulties of deglutition are very much diminished. 6. Neuralgia. Painting with guaiacol seemed to give good results in sciatica, in intercostal neuralgia, and in coxalgia. Balzer employed the following ointment in bennorrhagic orchitis: Guaiacol, seventy-five grains; vaseline, four hundred and fifty grains. In the very painful forms he applied the first painting over the abdomeno-inguinal region with from thirty to forty-five grains of pure guaiacol, and after the first sharp burning relief generally occurred at the end of about half an hour.

These, says the writer, are the affections in which guaiacol has been employed. The dominating action of the drug is antithermic. This has been observed especially in cases of tuber-

Smoker's Vertigo.—At a recent meeting of the Congrès des sociétés savantes, a report of which appeared in the Progrès médical for May 4th, M. Kolos said that vertigo caused by nicotine was very frequently observed, and that it manifested itself sometimes under the form of a slight acute poisoning accompanied with pallor, salivation, cold sweats, headache, vertigo, staggering, etc., which symptoms were produced in those who smoked for the first time; sometimes the poisoning was more serious, as, for instance, in the case of a man who had smoked twenty-five pipes on a wager, who suffered for many months with vertigo. The vertigo of chronic intoxication from tobacco, he said, might be observed in the workmen and women in tobacco factories, as well as in smokers, in snuff-takers, and in those who chewed tobacco. The action of nicotine varied according to the amount absorbed, and the disturbances caused in the life of the cells in consequence of their contact with the poison might also be variable.

M. Le Roy de Méricourt remarked that he had never observed smoker's vertigo in Brittany or in certain other countries in which he had lived for a long time, but he had observed a tendency to syncope dependent upon disturbances of the circulation following intoxication with the ordinary tobacco.

The Intermediary Nerve of Wrisberg.—At a recent meeting of the Académie des sciences, a report of which is published in the Gazette médicale de Paris for May 4th, M. A. Cannieu remarked that the nerve of Wrisberg had been the subject of much discussion. According to some authors, it was a motor nerve; to others, a sensory nerve. In 1878 M. Mathies Dural had made out an aberrant branch of the glossopharyngeal nerve to the sensitive centre to which, according to him, the intrabulbar fibres of this nerve were directed. Having made some researches, said M. Cannieu, on the internal car, he had observed certain facts which enabled him to confirm this interpretation. Thus, among rodents he had ascertained the existence, which had been denied up to that time, of the intermediary nerve of Wrisberg; on the other hand, among bony fishes he had seen the cellular extensions united in bundles which, he said, should be considered homologous to the intermediary nerve of W. Wrisberg and as an aberrant branch of the glossopharyngeal nerve.

The American Laryngological Association will hold its seventeenth annual congress in Rochester on June 17th, 18th, and 19th, under the presidency of Dr. John O. Roe, of Rochester. The programme includes the following papers: Foreign Bodies in the Esophagus, by Dr. Harrison Allen, of Philadelphia; Dedicated Thyrеoids in Goitre, by Dr. E. Fletcher Ingalls, of Chicago; The Influence of Chronic Diseases of the Throat upon Certain Defects of Speech, by Dr. D. Bryson Delavan, of New York; Electrolysis by a Current Controller for the Reduction of Spurs of the Nasal Septum, by Dr. W. E. Casselberry, of Chicago: Is Acute Amygdalectomy in any way Dependent upon the Rheumatic Diathesis? by Dr. George B. Hope, of New York; Some Remarks on the Removal of the Tonsils—A Case of Lipoma of the Larynx, by Dr. J. W. Farlow, of Boston; A Case of Melancholia Cured by Intranasal Operation—A Case of Suppurative Ethmoid Disease followed by Invasion of the Sphenoidal Sinus, Abscess of the Brain, and Death, by Dr. F. H. Bosworth, of New York; A Consideration of Some of the More Important Principles of Intranasal Surgery, by Dr. W. K. Simpson, of New York; Ludwig's Angina, by Dr. J. E. Newcomb, of New York; a discussion on Tuberculosis of the Upper Air-passages, by Dr. Jonathan Wright, of Brooklyn, Dr. C. C. Rice, of New York, Dr. E. L. Shurley, of Detroit, and Dr. J. W. Gleissmann, of New York; Cyst of the Maxillary Sinus, by Dr. Charles H. Knight, of New York; A Case of Abscess of the Frontal, Ethmoid, and Maxillary Sinuses, by Dr. J. H. Bryan, of Washington; Necrosis of the Middle Turbinates—Congenital Osseous Stenosis of the Naris, by Dr. A. B. Thrasher, of Cincinnati; A Naso-pharyngeal Cyst—An Oro-pharyngeal Cyst—Fibroma Papillare, or True Papilloma, of the Nasal Septum, by Dr. Jonathan Wright, of Brooklyn; a discussion on The Relation of Vaso-motor Disturbances to Diseases of the Upper Air-tract, by Dr. F. H. Bosworth, of New York, Dr. W. H. Daly, of Pittsburgh, and Dr. J. N. Mackenzie, of Baltimore.

celiosis, although this action of the drug is successful in other pyrexias. The analgetic action of guaiacol must not be overlooked, for it has rendered great service in certain painful affections in the treatment of which we have often been powerless to combat the element of pain with other drugs.

Naphthaline in the Treatment of Worms in Children.—The Revue internationale de médecine et de chirurgie pratiques for April 25th contains an abstract of an article by Dr. A. Schmitz, which was published in the Jahrbuch für Kinderheilkunde. The author enumerates the principal symptoms caused by the presence of these intestinal worms and cites the opinions of authors who have demonstrated that it is not in the rectum or even in the large intestine generally that these worms are habitually found, but in the upper part of the intestinal canal, and that local treatment by the rectal canal rarely attains the purpose for which it is employed. Naphthaline, being a very energetic antiparasitic and possessing at the same time the property of being insoluble in water, may, thus, introduced through the stomach, pass through the intestinal canal without being decomposed. These qualities, says the writer, suggested to Ungar the idea of employing naphthaline in the treatment of worms, and he related the results of his researches to Dr. Schmitz, who employed the method in the following manner: After having purged the patients several times he prescribed from eight to ten capsules of naphthaline in doses of from 2-4 to 6-4 grains and more, according to the age of the child. Four of these capsules were taken during the day. Eight days afterward the same dose was repeated, and after a second interval of fourteen days a third dose was taken. In some rare cases, he says, a fourth dose may have to be given. The naphthaline should not be given immediately after meals, and oily or fatty food should be avoided, in order not to cause decomposition of the drug in the digestive canal and thus hinder its action. If it causes constipation a purgative should be given. In forty six cases in which this treatment was used, twenty-six children were completely cured. In twenty other cases the results were less favorable; the symptoms were ameliorated, but there was no definitive cure. In three of the cases the return of the symptoms was so long delayed that they were thought to be cases of reinfection. In cases where success is doubtful Dr. Schmitz recommends repeating the treatment after an interval of several weeks, as the organism of children tolerates repeated doses of naphthaline very well. In one case only it caused strangury, but the symptoms were slight and transitory. The action of naphthaline is always more certain than that of santouine, and it is much less toxic. In all the cases treated enema were not administered, but the administration of naphthaline through the stomach may be combined, with good results, with deep irrigations, according to Legar's method, especially when the patients suffer greatly from parasites that have penetrated deeply. Ungar employed for these irrigations aumuminum acetate in the proportion of a dessert-spoonful to eleven spoonsful of water. This astringent liquid kills the parasites situated in the deep parts of the digestive canal very quickly and allays the irritation of the intestinal mucous membrane.
A CASE OF Filaria Sanguinis Hominis, WITH CHYLURIA, TREATED SUCCESSFULLY WITH METHYLENE BLUE.

By AUSTIN FLINT, M. D., LL. D., PROFESSOR OF PHYSIOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK; VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

My election to the presidency of the New York State Medical Association for 1895 carries with it the honor of presiding over the meeting of the Fifth District Branch. My thanks for this evidence of confidence and regard on the part of the fellows of the State association can be more appropriately expressed on another occasion. At this meeting I shall content myself with endeavoring to add a little to the value and interest of your proceedings by reporting an unusual case with a novel method of treatment. I beg that you will accept this small contribution as an evidence of my appreciation of the privilege of presiding over your deliberations and discussions to-day.

I find in my records of thirty-three years ago (March 20, 1862) brief notes of an examination of a specimen of chylous urine sent me by the late Dr. Isaac E. Taylor. About two years later I had an opportunity of examining another specimen from the same patient, the urine still being chylous. I have no notes of the history of this case beyond those of the examinations of the urine; and I regarded it simply as a curious observation. In the works on urinary diseases, a number of cases of chylous urine had been reported with no very definite ideas of the pathology or the therapeutics of this condition. Nearly if not all these cases had resisted a great variety of measures of treatment. It was stated by all writers, however, that chylous urine was peculiar to tropical countries.

Before 1868 I did not keep a full record of my urinary examinations, but I had never seen a case of chylous urine before I examined the specimens sent to me by Dr. Taylor. I now have records of examinations of urine of eight hundred and twenty-eight patients in private practice since 1868. During fourteen years' experience as medical examiner for a life insurance company (1871 to 1885) I examined the urine of about two thousand applicants for insurance, who supposed themselves to be in perfect health. I never met with an instance of chylous urine, except in a specimen which I examined in March, 1894, in probably more than three thousand examinations.

The pathology of chyluria and its relations to the Filaria sanguinis hominis was first described by Timothy Richards Lewis, Surgeon Major, H. M. Army, in an article entitled On a Hematozoon Inhabiting Human Blood; its Relations to Chyluria and Other Diseases. Calcutta: Government print, 1872. A more complete account is given by Lewis in Quain's Dictionary of Medicine, article Chyluria. In 1861-'62, Dr. Vandyke Carter attributed chyluria to a direct admixture of chyle and urine, "a leak from the lymphatic tract into the urinar." In 1870, Lewis found, in a specimen of chylous urine, "numerous microscopic nematoid worms in a living condition"; and in 1872 he found a number of the same worms "in a state of great activity on a slide containing a drop of blood from the finger of a Hindus." In recent works on pathology, the parasites are described as larva of Filaria Bancrofti, a threadlike worm, eight to ten centimetres long, which inhabits the lymphatics of the serotum and lower extremities, and is said to cause lymphocytiasis, with edema and a thickening of the tissue of the nature of elephantiasis, or lymphatic abscesses, chylous hydrops, and chylous ascites. The ovum or larva—Filaria sanguinis—pass from the lymphatics of the serotum and extremities to the rest of the lymphatic system and to the blood (into the latter, however, for the most part, only during rest at night), and may then give rise to haematuria, chyluria, and chylous diarrhoea (Weichselbaum, Pathological Histology, London, 1895, p. 180). The larva found in the blood are in active movement and have "a length of 0.24 millimetre and a breadth of 0.0075 millimetre, a rounded-off head with a tonguelike process, and a pointed tail."

It is stated by all observers that in patients affected with Filaria sanguinis the parasites disappear from the blood during the daytime and reappear at night; but when the patient sleeps during the day and is active during the night, the parasites appear in the daytime and are not found at night. According to universal experience the results of treatment have been unsatisfactory.

On March 3, 1894, I received from Dr. Joseph N. Henry, of New York, a specimen of chylous urine. I made an examination of this urine with the following result:

The specimen was white and opaque, like milk, with a very slight reddish-yellow tinge. The reaction was acid and the specific gravity 1021.5. There was no ominous odor. A portion of the urine agitated with an equal bulk of ether became nearly clear. The specimen contained thirty-nine per cent, in volume of albumin. The albumin being removed and the urine filtered through animal charcoal, the filtrate was found to contain 7.25 grains of urea per fluidounce. There was no sugar. On standing for twelve hours, there was a whitish sediment streaked with red. Microscopical examination revealed minute fatty granules, red blood-corpuscles, a very few oil globules, a very few leucocytes, and bacteria.

I reported to Dr. Henry that the specimen was chylous urine, probably from a native of the tropics, and associated with Filaria sanguinis. Dr. Henry invited me to see the patient, and has sent me a history of the case.

Having had considerable experience in the use of methylene blue in malarial disorders, and in view of the action of this remedy on the Plasmodium Malariae, it occurred to me that it might have a similar effect upon the filaria. I accordingly suggested to Dr. Henry to give the patient two grains of methylene blue every four hours dur-
ing the day, and to note the effect upon the patient and upon the parasite.

The following history was sent to me by Dr. Henry:

J. H., born in the Isle St. Kitts, West Indies, twenty-two years old, colored, well developed and muscular; occupation, bar porter; ten months in this country; family history good; never ill before; presented himself to me, March 2, 1894, with the following symptoms: Headache, pain in the small of the back, one degree elevation of temperature, with a history of rapid emaciation and muscular weakness. He handed me a specimen of his urine, which looked like rich milk, being perfectly opaque, with no tendency to precipitation. Chemical examination showed the following: Specific gravity, 1.014; reaction slightly acid; after filtration, approximately two per cent. of albumin; no sugar. Upon agitation of the urine with ether it became perfectly clear, demonstrating the presence of emulsified fat in large quantity. Microscopical examination showed large quantities of finely divided fat globules, chyle corpuscles, and a considerable quantity of apparently broken down matter. No casts were discovered, but there were a few blood-corporcles. From the foregoing history and symptoms I arrived at the conclusion that the patient was suffering from chyluria, a disease which is seldom found in the temperate zone, but is more or less frequently found in tropical or semi-tropical countries, my attention having been called to it by a case which I saw in Singapore some years ago, the disease being due to the fact that the lymphatics become the habitat of one or more animal organisms known as Filaria sanguinis hominis (this condition was first described by Lewis in 1872), and that the embryos are thrown out in large quantities into the blood current. I immediately began a series of examinations of the patient's blood. My first examination was made at the man's home on March 3d, at 12.30 A. M., it being a well-recognized fact that the embryonic filaria is rarely if ever found during the daytime in the blood of the sufferer, unless through his occupation he inverts the usual order of his life and works during the night; then they may be found in the blood during his period of rest from physical and mental labor—that is, during the day. I first took one specimen of blood from the right ear, placing it under a one-eighth-inch objective, I found in each field of the microscope an average of ten embryonic filariae. Their diameter was that of a blood-corpuscle, their length being from forty to fifty times their diameter. Their movements were extremely rapid, twisting and turning and quickly moving out of the field of vision. They seemed to have a well-marked head, a cylindrical and striated body, terminating in a filament-like tail.

On the following day I called the attention of Dr. Austin Flint and Dr. Austin Flint, Jr., to the case. Dr. Flint suggested the use of methylene blue in the treatment. On March 5th I administered to the patient two grains of methylene blue, and repeated it at intervals of four hours during the day. The same night, at eleven o'clock, the doctors Flint and I examined the blood with the microscope, and, after searching four slides carefully, we were able to discover but two filariae, they being extremely sluggish in their movements at that time and stained a decided blue, as was also the blood plasma to some extent. The urine in the meantime had entirely lost its milky and turbid appearance and had become perfectly transparent, but deeply stained with the characteristic greenish blue. The treatment was then discontinued, the blood being examined during the 8th and 11th of March without finding any traces of the embryonic filariae. On March 12th the urine had lost its blue color and again became milky. On the night of March 13th microscopical examination revealed the embryonic filariae in a considerable number; but at the same time there was considerable aniline staining, and their movements were much more sluggish than they were when I first had occasion to examine the blood. On that night I was accompanied by Dr. D. H. McAlpin, who took a specimen of blood to the Carnegie Laboratory for micro-photography.

On the following day the patient was again given the methylene blue, and on the third day thereafter the blood was examined for the organisms. Several dead and partially disintegrated filariae were found deeply stained with blue. The urine had entirely cleared, being found normal on chemical and microscopical examination, except its deep blue stain. The treatment was discontinued at the expiration of five days, and, despite the fact that repeated microscopical examinations have been made, the embryonic filariae have up to the present time (April, 1894) not reappeared. The urine remains normal, the patient having regained apparently perfect health.

The effects of the methylene blue in this case were decided and prompt. After the administration of two grains every four hours during the day on March 5th, the parasites were very few at 11 P. M.; the only two found were deeply stained with blue and their movements were extremely sluggish, the urine being clear but intensely blue. On the fourth and the seventh days no parasites were found, although the treatment had been discontinued after the first day. On the eighth day the urine became milky, and on the night of the ninth day the parasites were found in great number, but their movements were not very active. On the tenth day the treatment was resumed and continued for five days. Three days after, the blood being examined at night, a very few motionless filariae were observed. Since that time, and up to the present writing, the urine has been normal, and the patient has been restored to perfect health.

Judging from this single case, it appears that methylene blue is a prompt and efficient remedy for chyluria dependent upon Filaria sanguinis hominis. In this instance more than a year has now elapsed without a return of the disease. This single experience points to the possibility of benefit from methylene blue in the treatment of other diseases due to the filaria, such as chylous collections in the peritoneal cavity and in the cavity of the tunica vaginalis testis, hematuria, and elephantiasis.

About two years ago I made an observation on a perfectly healthy subject on the effects of methylene blue on the urine. An hour and a half after taking a grain and a half of methylene blue the urine was distinctly colored. In two hours and a half the urine was intensely blue. The methylene blue was continued, a grain and a half three times daily, for three days, and twice daily for four days, without the slightest inconvenience. It was discontinued at the end of the seventh day. The urine gradually lost its blue color, but it did not disappear until about forty-eight hours after the last dose. During the administration of the drug the faces were colored blue.

I have used methylene blue with success in malarial enlargement of the spleen, in chronic cystitis, and in a few cases of gonorrhoea. I have given it in doses of a grain and a half to two grains in capsules two or three times daily. In a few cases it has produced some irritation of the neck of the bladder, but this has been exceptional. It has been recommended to give about thirty grains of powdered nutmeg with each dose of methylene blue, to
guard against bladder irritation. In cases in which any trouble of this kind has occurred I have corrected it easily with nutmeg. In malaria it has been found that methylene blue directly attacks the plasmodium and promptly relieves the symptoms in many cases; but the good effects are not so lasting as when the condition is overcome by quinine. This has been my experience; but in some cases of enlarged and painful spleen of malarial origin, which have resisted quinine, the methylene blue has acted promptly and most satisfactorily. Having used this remedy for seven or eight days, I have discontinued it and substituted quinine in moderate doses and continued for several weeks, with excellent results.

I give my experience with methylene blue in gonorrhea with great diffidence, for the reason that my opportunities for testing it have been small, and the results in the hands of others to whom I have suggested its use have not been entirely satisfactory. My attention was directed to its use in gonorrhea by an article by Dr. Max Einhorn, which appeared in the Medical Record for November 1, 1891. I was specially struck with the logic of this treatment for gonorrhea, as both methyl blue and methylene blue are used largely in staining the gonococcus. Urethral injections of methyl blue have been employed by Adler and others with only moderate success, not enough to popularize the use in this way of a remedy so troublesome and uncleanly. It seemed to me, also, more rational to use it internally, according to the method of Dr. Einhorn, impregnating the urine strongly with it, and depending upon the frequent passage of the agent in this form over the affected surface. In a few cases of gonorrhea which were incidental to other diseases in the medical wards of Bellevue Hospital, I used methylene blue alone internally with great success. I kept no records of these cases and have records of but a few cases in private practice. The few cases that I have treated have been uniformly successful with one exception. This patient had repeatedly suffered from gonorrhea and had a stricture and probably ulcerated spots in the urethra. He took methylene blue, a grain and a half, twice daily. It seemed at first to relieve him, and the discharge disappeared. On the ninth day, however, he drank some whisky, and the discharge returned. He then took santal Midsy, and the discharge was promptly arrested. I saw him but once, and he was exposed to considerable fatigue during the entire time of his trouble, traveling on business.

In two of my recorded cases the effects of the remedy were truly remarkable:

The first case was that of a man, thirty-five years of age, with a moderate but characteristic discharge which had existed for two or three days. He was put on methylene blue, a grain and a half three times daily, and had no other treatment. The next day the discharge was very much diminished and the ardor urine had disappeared. I saw the patient again on the ninth day, and he was perfectly well. He stated that the discharge ceased on the fourth day. At the beginning of the treatment I suggested, as an experiment, that he continue his usual habits of moderate use of alcohol, with the idea that the impregnation of the urine with the remedy would counteract any local effects due to alcoholic indulgence. He told me, how-

ever, that for domestic reasons he was unwilling to submit to any experiment which could possibly retard a cure.

The second case was that of a man, fifty years of age, with his first attack, who was seen by me on the first day. In this case the gonococcus was discovered in the urethral discharge. The patient took two grains of methylene blue three times daily for three days and twice daily for four days. He drank wine, beer, and occasionally spirits habitually. He readily assented to my proposition to drink as usual, and on the first day of treatment drank freely of wine and beer. During the last four days of treatment he exceeded his instructions to the extent of drinking very freely, once or twice to excess and even to the point of gross intoxication. There was great diminution in the discharge on the first day of treatment, and the patient was entirely well on the seventh day.

The cases of gonorrhea that I have treated in private practice have been in patients who had regarded me as their physician and were unwilling to make their troubles known to a stranger. I have treated these cases more or less under protest, with the understanding that they were to go to a specialist if the disease did not progress favorably toward a cure. My treatment was, indeed, experimental (but with the full knowledge and consent of the patients), as I do not pretend to treat gonorrhea according to the modern accepted methods. My small experience, however, goes to confirm the observations of Dr. Einhorn, although I used methylene blue instead of methyl blue. It seems to me that the agent used will attack and destroy the gonococcus unless the organism has penetrated deeply into the mucous membrane. It must be, it would seem, an efficient therapeutic measure to secure the passage of urine, strongly impregnated with an agent destructive to the specific cause of the disease, frequently over the entire mucous surface affected. Immoral as it may appear, and certainly improper to suggest to the laity, it is a reasonable scientific proposition, which is suitable for this time and place, that methylene blue would probably act as a prophylactic against gonorrhea infection in impure intercourse.

I fear that I have exceeded the limits of length which are justified by the small actual material on which this address is based; but I have thought it better to occupy your time with a slight contribution to the scientific proceedings of the association than to endeavor to entertain you with generalities which might be neither useful nor interesting.

WHAT IS THE SIGNIFICANCE OF THE SPLASHING SOUND OF THE STOMACH?

By A. ROSE, M. D.

(From Dr. Max Einhorn's Clinic in the German Dispensary.)

The splashing sounds of the stomach are produced when water and air are agitated together, when either the whole body or the stomach alone is shaken. The latter is done when we tap with the fingers on the relaxed abdominal walls over the stomach. To obtain the splashing
sound by means of such tapping the patient must be in the recumbent position. The sound, however, can also be produced by shaking the whole body while the patient stands upright.

The symptom in question can be elicited in most people of ordinary good health shortly after they have taken liquids or fluid food. By itself alone, therefore, it is not to be considered as a pathological symptom. In some people a splashling sound can be produced a considerable time after eating, immediately after they have swallowed from fifty to two hundred grammes of water. That, however, is abnormal.

In regard to those peculiar splashing, gurgling, or croaking noises of the stomach which some persons can develop by means of abdominal pressure, and which excite the attention of laymen, and even of some physicians, Kussmaul says: "There are many persons, whose stomachs are either of normal dimensions or dilated, who have attained great skill in causing such noises. By means of their abdominal muscles they make a horrid music with every contraction or expansion of the abdominal wall, a music which can be heard at some distance. It is a cooing, croaking, belching, and receives the most fantastic explanations; the presence of live frogs in the stomach and the like are sometimes thought of. In hypochondriacs it gives rise to sombre imaginations, and hysterical persons take advantage of it to create a sensation or admiration by such ventriloquism."

Baradat de Lacaze, on examining patients from different wards who did not suffer from gastric disorders, found that he could produce the splashing sound regularly for two hours after liquid food had been ingested, and for six hours after full meals composed of both liquid and solid food. As we shall see presently, my own observations, made on a hundred patients, do not correspond with the results obtained by this author.

Oser observed that in cases of gastric atony the fluctuation of small waves could be elicited for four or five hours after a full meal, and Baradat de Lacaze stated that the splashing sound could be produced for two hours after small meals, and as long as six or seven hours after full meals, in all cases in which the passage of food from the stomach was retarded.

Malbran questions whether this symptom is necessarily pathological; still, he admits its significance if it continues under certain conditions.

The same author remarks that during infancy the splashing sound can be produced in the large intestine if distended by gas; that it can not be exactly localized by the ear in cases of infants. He denies that the splashing sound of the stomach and the gurgling noise of the intestine in infants can be distinguished with certainty. He also reports six cases in which the autopsy had shown the possibility of errors in this regard. In these six cases the splashing sound had been produced during life in the colon half filled with semi-liquid fecal matter.

When the new methods of examination of the stomach were first introduced, it was assumed that the splashing sound elicited below the umbilicus in dyspeptic persons meant dilatation of the stomach.

In speaking of dilatation of the stomach, ectasia ventriculi, most authors at present understand by this term a typical condition in which the food stagnates in the stomach, in which the ingesta taken the day previously, or before, are found on washing out the stomach in the morning.

Dr. Einhorn* has enumerated the terms used by different authors to designate a pathological condition of the stomach not which only comprises an anatomical feature, as the word dilatation implies, but which is characterized by a much more important lesion of the mechanical functions of that organ. These terms are: "dilatation of the stomach," "anatomical and clinical dilatation of the stomach," "ectasia ventriculi," "insufficiency of the stomach," "gastro-intestinal insufficiency of the first and second degree." He himself uses the word "isochylinia" (isochyn, to retain, and χυλός, chyme) for a prolonged stagnation of chyme in the stomach, to designate a complex of symptoms without stating the cause.

Moreover, since we distinguish between dilatation and atony of the stomach, or myasthenia gastrica, the symptom of splashing sound by itself alone does not suffice to indicate dilatation, or atony, or myasthenia. The symptom, however, is important for determining the lower border of the stomach, the low position of the organ when exceptional causes, such as tumors, can be excluded. It is of diagnostic importance, as it indicates relaxation of the muscles of the stomach in cases in which it can be easily produced over a large area. If found while the stomach is free of food it is, except in instances of continuous supersecretion, a means of diagnostiating myasthenia gastrica.

Barring cases of continuous supersecretion, the chemical examination of the contents of the stomach will not suffice for the diagnosis; on the other hand, the presence of the splashing sound by itself alone is only of value as an adjuvant in diagnostiating the abnormal state of the mechanical functions of the stomach. We know that this mechanical part has the greatest and paramount influence on the further process of digestion; if only this part is normal, other conditions lacking, digestion may go on all the same without material disadvantage. Therefore the examination for the splashing sound will be indispensable; it will always be of supreme importance whenever we examine a patient for gastric disorder.

Directly and by itself alone the splashing sound, whenever it can be produced, is a means of diagnosis for determining the lower border and the dimensions of the stomach.

Together with Dr. Einhorn I have in the latter's clinic in the German Dispensary (medical department—men) examined a hundred patients without selection for the splashing sound, in accordance with the following scheme: I wrote down how long a time previously the patient had

---

* Diagnosis and Treatment of Stenosis of the Pylorus. Medical Record, January 19, 1895
partaken of food; then we examined the patient for the splashing sound—first, without giving him water to drink. If the symptom could not be elicited, the patient was given half a glass of water and then examined again. We noted whether the symptom could be produced easily or with difficulty. After I had recorded the result in my table, I wrote down the diagnosis of the case from the dispensary record.

The following is the table of a hundred cases examined for the splashing sound:

</tbody>
</table>
In thirty cases no splashing sound could be elicited. In six of these food had been taken only from one half to two hours before examination. In two cases no result was obtained on account of invincible tension of abdominal wall. In one case the symptom was found six, in two seven, in one eight, and in one twelve hours after eating. In sixteen cases the splashing sound could be elicited as far down as or below the umbilicus. Out of these sixteen cases there were only nine in which gastric symptoms had been complained of. In thirty-three cases with splashing sound there were no gastric complaints. In three cases with grave gastric affections (two, carcinoma ventriculi; one, gastritis chronic) the splashing sound could not be elicited. In those two of carcinoma the examination had been made three and a half resp. two hours after eating.

Diseases of the stomach are often associated with diseases of the apparatus of circulation and the apparatus of respiration. In fact, all diseases of long duration and weakening character go together with affections of the stomach. Thus we find in our table, for instance, in twenty-four cases of heart and pulmonary diseases, splashing sound in nineteen instances.

Fatal Effects of Tight Lacing.—The Lancet for May 25th publishes the following account: A woman, eighteen years of age, was attacked on the 11th of May with pains in the stomach, and a physician was called to see her, who found her consciousness so tightly laced that it had to be broken off. She was taken home and treated, but she died on the 12th. At the post-mortem examination an ulcer was found in the stomach, which the physician attributed to tight lacing.

EXPLORATORY PLEUROTOMY AND RESECTION OF COSTAL PLEURA.

By CARL BECK, M.D.

Henry W., four years of age, was sent to the surgical division of St. Mark's Hospital on June 6, 1894. The family history revealed that the patient's father was in good health and that his mother had died from pleuro-pneumonia. From the report of the family physician it was learned that the patient had been sick since January 29, 1894, when he was seized with pleuro-pneumonia, which ended in a crisis about February 7th. The temperature (from the attack until June 6th) varied between 99° and 102° F., and symptoms of compression, such as dyspnoea, dullness, and weakened respiration, were always more or less present. On the strength of these symptoms pyothorax had been diagnosed, and accordingly thoracotomy was advised by the family physician.

On June 6th, when I saw the patient for the first time, I found the following condition present:

The boy was enaciated and showed a slight retraction of his thorax on the left side. The circumference at the nipple was twenty inches, each side comprising ten inches. Respiration, 62; pulse, 55; temperature in ano, 101° F. By palpation the vocal fremitus was found increased on the left side and slightly diminished on the right side. Anteriorly on the right side the whole area situated above the upper border of the third rib, as well as the axillary region, was found to be tympanitic on percussion, while the area below was normal. Posteriorly the percussion note was vesico-tympanitic above the fifth rib and normal below.

On the left side dullness was found anteriorly from the apex to the base. Auscultation on the right side revealed roughened respiration and fine moist rales over the whole chest. The
vocal resonance was slightly diminished. On the left side distant respiration without change could be heard, while the vocal resonance was slightly increased.

Crepitant rales could be distinctly heard over the whole left side. They were accompanied by fine moist rales. The dulness was most manifest over an area extending from the upper border of the seventh rib and from the manillary line to a point situated about an inch back from the posterior axillary line.

The heart was slightly displaced toward the right side. The first sound was short, high in pitch, and metallic in quality. The pulmonic second sound was accentuated. The aortic sound was normal.

In the light of this status process, the diagnosis "pyothorax" was obvious. The most important means of verifying this diagnosis, exploratory aspiration, had, however, not been tried yet.

After the whole left side was well disinfected, an exploratory needle, which had been rendered dry and aseptic by holding it over an alcohol flame, was introduced in the fifth intercostal space between the anterior and posterior axillary lines. Considerable resistance could be noticed as soon as the needle had passed the intercostal space. As only one drop of a slightly yellowish fluid was drawn, the aspiration was repeated two inches lower down in the same line and with a negative result. After having inserted the exploratory needle seven times on different portions of the dull area, I refrained from further procedures at the time. Knowing the frequency of diagnostic errors in such cases where, in spite of the negative result of a few aspirations, pyothorax was present, I was not yet convinced of the absence of pus.

Every physician who has had much experience in pyothorax will admit that in spite of the most minute consideration of all diagnostic rules bearing upon this subject, he will often be surprised by the result of the exploratory puncture. It may happen, in fact, that all the classical symptoms, as they are described so well in text-books, are absent, and still pyothorax is detected at last. Repeatedly I have found pus only after a considerable number of aspirations were made; so, for instance, in a case where the cavity was almost filled up with a cheesy mass, the liquid pus present amounting to a trifle only. In such a case it is natural that the needle, by being introduced into these solid masses, can not draw any pus (vide article on Pyothorax, Medical Record, May 19, 1894). The same negative result can be obtained in a case where there are large fibrinous masses in serious effusions.

It has, furthermore, to be considered that there are exceptional cases of pyothorax where the pus cells have settled down like a sediment to the bottom of the abscess cavity, while above this a collection of a clear serous fluid is found, which, if aspirated, would necessarily leave the surgeon under the conviction that no pyothorax existed at all. Such misapprehension may come all the easier if the exploratory puncture is made high up. This fact teaches that punctures should be made below as well. It should then, however, not be forgotten that just in the most dependent part the clots which settle there are likely to clog the exploratory needle. If in such a case absorption of the fluid should take place, and the sediment-like pus should under-go thickening at the same time, the result of the aspiration, being negative, would ordinarily give no information as to the true state of the pleural cavity.

To continue the history: On the following day I repeated the exploratory aspiration five times over the dull area with the same result as before. Some elucidation was expected from the bacteriological investigation of the drop which had been drawn at the first aspiration; but the bacteriological examination revealed the absence of pathogenic micro-organisms, and under the microscope only blood and lymph cells were detected. Similar investigations were made after each of the negative aspirations in this manner: a syringe was filled then with sterile water, which was discharged into a Petri's plate containing gelatin. This was done in the expectation that, in case cheesy masses were present, small particles of them would be forced into the calibre of the needle, in or on which they could not be perceived microscopically; but, by being mixed with the sterile water, they could possibly be recognized by the aid of the microscope. But this experiment proved to be negative also.

What diagnosis could be made now on the basis of these examinations? The history showed that there was an inflammatory process, probably followed by the formation of an effusion. Considering the fact that effusions in the pleurse of children are almost invariably of a purulent character, it was obvious to assume that a pyothorax had been present, the liquid contents of which were absorbed by this time. Another question was, Were the solid contents absorbed also, and was the dullness only the expression of thickened pleural tissue, or was it the expression of cheesy masses the existence of which could not be demonstrated by our insufficient diagnostic means? In favor of a thickening of the pleura was the great resistance experienced whenever the needle was introduced; but then it had to be considered that both conditions alluded to could be combined just as well. If so, was it wise, then, not to interfere with the further process of absorption of cheesy material which predisposes so much to tuberculosis? The possibility of the existence of a subpleural abscess or of an echinococcus of the lungs could with all probability be excluded. Neoplasms, such as carcinoma, sarcoma, or lymphoma, could also be excluded by regarding the acute onset of the disease. Tuberculosis did not appear to be probable, as neither in the sputa nor in the aspirated drop was any evidence of the presence of the tubercle bacillus found.*

So, considering the difficulties of diagnosis in this case, I did not see why, if everybody admits the necessity of exploratory incisions in abdominal surgery and lately also in the precarious field of brain surgery, the pleural sac should not enjoy the same privilege. What is to be feared most in an incision of this kind is the formation of pneumothorax. But this accident would hardly occur in pleuritis, where the presence of adhesions would prevent unintentional opening of the thorax. Under strict aseptic precautions even this accident, however, would not necessarily need to be feared, as pneumothorax would disappear soon after the wound was closed, as the lungs would then expand readily. So, for

---

* This, however, could not be regarded as an absolute proof for its non-existence, as in serous effusions this bacillus is but exceptionally found. Even in cases in which tuberculosis has been well demonstrated by other diagnostic means, ounces of freely drawn effusions have been injected into the peritoneal cavities of rabbits without producing the slightest symptoms of tubercular infection.
instance, have I never met with any dangerous symptoms due to pneumothorax in five cases of subphrenic abscess where I, after resection of a rib, opened the pleural sac before I had incised through the diaphragm. In the case of a very much emaciated patient the symptoms of shock became evident as soon as after opening of the pleura air rushed into the pleural cavity with considerable noise, so that I deferred incision of the subphrenic abscess until the following day, whereafter the patient made a good recovery.

On June 9th, under minute aseptic precautions, an incision was made above the fifth rib, reaching from the mamillary line to the posterior axillary line, where the dullness was most distinct. A piece of rib, four inches in length, was resected subperiosteally. The posterior portion of the peristemum was then divided, so that the costal pleura came into view. Careful dissection revealed the presence of thick fibrous tissue, which was cut off by conducting the knife flat upon the pleura about in the way a chiroepistist holds his knife. The knife lost its edge by cutting this tissue on account of the cartilaginous, partially even calcareous, condition of the pleura. After the flat incisions were repeated about a dozen times, thus constantly removing pleural tissue, a point of softer consistence was reached. The diameter of the resected pleural tissue amounted to nearly an inch.

By now introducing a flat probe 'to the point adluted to, it was revealed that the inner surface of the costal and the external surface of the pulmonary pleura were loosely attached to each other by adhesions. By pushing the probe farther back it was easy to lift the posterior surface of the costal pleura from the corresponding anterior surface of the pulmonary pleura by tearing the adhesions. But it had naturally to be presumed that this fibrous condition of the costal pleura extended much farther. Therefore, as anesthesia was borne very well, the fourth and sixth ribs were removed also for the same length as the fifth was. Then, by lifting up the costal from the pulmonary pleura, and after having introduced a blunt elevator through the incision in the costal pleura, it was easy to excise the degenerated costal pleura by means of the rib shears. The average diameter of the margins of the excised pieces amounted to half an inch. No effusion and no cheesy masses were found anywhere in the pleural cavity. After the field of operation was made clean by gauze moss dipped in sterilized water, the edges of the wound were united by a continuous silk suture, leaving a few sterilized wicks in each corner of the wound. Then, by means of sterile gauze and of a large piece of absorbent mossboard, compression was exercised upon the resected area.

No reaction followed which could be attributed to the wound. The dyspnea was not relieved until forty-eight hours afterward, when the number of respirations went down to 40. The average temperature had been 101° F. and the pulse 120 within these two days. On changing the dressing three days after the operation no reaction was found in the wound. When the wicks were withdrawn a few drops of serum were discharged. The wicks were not replaced. Two weeks after the operation the following condition was made out: Union by first intention was obtained. The temperature was normal and the pulse-rate was 96. The general condition of the patient had improved. Above the resected areas the dullness was much less distinct than before, while the respiratory sounds were very distinct. Dyspnea was still present, but slight.

The patient was discharged from the hospital a week later, after having gained three pounds. He remained well until the 29th of November, when he was taken ill with bronchitis. At that time he was examined by Dr. Reynold W. Wilcox, of this city, who reported to me that the respiratory sounds were very much more distinct over all the directions indicated by the cleftrix on the left side. The same condition was ascertained by Dr. Morvay Rottenberg, of this city, who also had the kindness to examine the child on December 24th.

On May 10, 1895, when we had a chance to examine the patient again at my clinic at the New York Post-graduate Medical School, it was found that the dyspnea had disappeared entirely. Auscultation did not reveal any abnormalities. Only slight dullness above the resected area was still noticeable. The general condition of the child proved to be excellent.

As there can be no doubt that exploratory incisions of the pleura, if done under the necessary precautions, will prove to be free from danger, they should be undertaken whenever there arises any such doubt as in the case reported. As to the diagnostic value of this method, it may be urged that in this case the exploratory incision proved the presence of an enormously degenerated pleura and the absence of solid masses. That the resection of thickened pleural tissue will relieve compression is also obvious. To what extent it can, however, be utilized in practice will, of course, not be pointed out by a single case. As the whole thickened area was not removed, a fair amount of degenerated tissue remained; but it appears to me that if only a portion of it, especially the thickest part—in other words, if a great obstacle to the free expansion of the lungs is removed, there are all chances of compensation.

37 East Thirty-first Street.

SOME PRACTICAL REMARKS CONCERNING THE TREATMENT OF INTERNAL HEMORRHOIDS.

BY JOHN E. DAVIS, M. D.,
COLUMBUS, M. S.

The first essential of success in the treatment of rectal diseases is a careful examination.

The physician who accepts his patient’s statement without a further examination, in the majority of cases will find their satisfactory treatment forever a sealed book.

Assuming, then, that a correct diagnosis of internal hemorrhoids has been made, we immediately divide them into the surgical and the non-surgical.

The latter division embraces, first, that class of hemorrhoids dependent upon diseased conditions elsewhere, such as stricture or cancer of the rectum, diseases of the prostate or bladder, the pressure of a gravid uterus, uterine or ovarian tumors, or cirrhotic conditions of the liver.

In such conditions an operation is useless, and the efforts of the physician should be directed toward a removal of their cause.

Again, we have a class of patients who suffer only mildly from hemorrhoids—that is, they are not very appreciably inconvenienced by pain, uneasiness, or hemorrhage. For such patients an operation is hardly indicated, and all that is necessary is to pay attention to their diet and to the condition of their bowels.

Where patients suffer from hemorrhoids that are inflamed or strangulated, the condition is really one of infec-
in the present day. All irritation of the anal region should be carefully avoided, and the bowels regulated by appropriate diet and the proper use of laxatives. Each evacuation from the bowels should be followed by an ablation of warm water, and, if the piles protrude, anoint with plain vaseline and replace them.

In this class of cases large injections of cold water (40° to 50° F.), either plain or medicated with boric acid or antipyrine, are productive of much good in the abatement of the inflammation, congestion, and in arresting small bleedings.

In the vast majority of cases of internal hemorrhoids, astringent injections or ointments are not only useless but absolutely harmful. Where the inflammation is severe or gangrenous, the application of warm water is indicated. In addition to the treatment enumerated above, some soothing topical application or ointment is nearly always indicated, especially when associated with severe pain. Wash the parts with a little warm water and apply the following ointment:

\[ \begin{align*}
\text{Oil of ipecacuanha} & \quad \text{gr. x} \\
\text{Petrolatum} & \quad \text{or equivalent} \\
\text{Unscented spirituous turpentine} & \quad \text{gr. iij} \\
\text{M.} & \\
\text{Ext. opii aq.} & \quad \text{ft. sup. no. j.}
\end{align*} \]

This now brings us to a consideration of that division of hemorrhoids best treated by surgical measures, which comprise by far the vast majority of the cases that consult the physician. Hence we say the scientific treatment of internal hemorrhoids is one that is essentially surgical, and the numerous methods devised for their treatment from time to time have been legion.

The injection method, which is so extensively lauded by certain practitioners, is both unscientific and dangerous, and has nothing to recommend it except that it is sometimes painless, but by no means always so. It is unsatisfactory because so often unsuccessful, and it is dangerous because you cannot regulate the inflammation produced, some of its consequences often being alarming to the patient injected, ultimately stricture, or else the production of a septic focus with the formation of venous thrombi, which become dislodged by defecation or some motion of the patient, are carried to the liver, and form minute abscesses. Thus patients not infrequently have died of hepatic abscess, septicemia, or pyemia, when their history, if understood, could have been directly traced to this painless subterfuge of quackery.

There are two methods of treating internal hemorrhoids, and only two, which have stood the test of time, and they are the ligature and the clamp and cautery, and a comparison of these two methods is the chief purpose of this article.

It is but fair to state, however, that the operation of excision devised by Whitehead is theoretically an ideal one, and in his hands has yielded most gratifying results, but for obvious reasons it is an operation that will never commend itself to the general practitioner. If we compare the ultimate results of the method by ligation with that by the clamp and cautery, neither has an advantage over the other, both yielding most excellent results. But we must make our comparison from the time of operation till the patient is well. In comparison to the clamp and cautery the method by ligation, in many cases, is both slow and tedious; hence the ease and rapidity of the former method are not without their apparent advantage.

If we compare the after suffering of these two methods, we have a decided advantage in favor of the clamp and cautery. Rarely after an operation by the clamp and cautery is it necessary to prescribe an opiate, and we all know how seldom it is after an operation by ligation that we are not compelled to administer such remedies. The fact that patients suffer so little in comparison to the method by ligation gives the clamp and cautery a decided preference.

Again, if we compare the time of confinement, the clamp and cautery still has the advantage. Seldom are patients operated upon by the ligature enabled to leave their rooms under two weeks, while with the clamp and cautery the majority leave in almost half the time. The clamp and cautery has these points of advantage: Ease and rapidity with which the operation can be performed, comparative absence of pain after operation, and the lessened loss of time from business. These are all points which do not fail to commend themselves to the observing surgeon, and have won for the clamp and cautery a widespread and growing popularity in the treatment of internal hemorrhoids.

The use of the clamp and cautery does not and cannot give better final results than the ligature, but it gives just as good. Both methods are simple, the final results of both the same, and the ligature has only this point of advantage—that is, it requires no special instrument for its performance.

In operating with the clamp and cautery, after cleaning out the rectum and paralyzing the sphincter muscle, grasp the pile tumor with forceps and bring it well down, then with scissors incise the mucous membrane around the lower border of the tumor. Apply the clamp, excise the tumor to within a quarter of an inch of the clamp, and then cauterize. Slightly loosen the clamp, and if there is any bleeding cauterize again. Always leave a margin of mucous membrane between the pile tumors cauterized. Of course, judgment must be exercised in the use of the cautery so as not to make the number of applications too numerous. When, however, the hemorrhoidal area is unusually extensive and involves the whole circumference of the anus, then Whitehead's operation is indeed an ideal one, and should be the operation selected for this class of cases.

The Death of Dr. Emil Noeggerath, formerly of New York, is announced as having taken place recently in Wiesbaden. Dr. Noeggerath was well known as the author of the theory of the origin of certain pelvic diseases of women in infection with "latent gonorrhea."
AN EXPERIMENTAL STUDY OF DIRECT AND INDIRECT FARADIZATION OF THE DIGESTIVE CANAL IN DOGS, CATS, AND RABBITS.*

BY S. J. MELTZER, M. D.,
NEW YORK.

(From the Physiological Laboratory of the College of Physicians and Surgeons, Medical Department of Columbia College.)

The electrization of the stomach or the intestines has for its purpose, among other things, the production of contraction in these organs. As is well known, two methods are at present employed in the electrical treatment of the digestive canal: the percutaneous and the direct electrization. In the percutaneous electrization both electrodes are placed outside, on the abdominal wall, in a manner which is deemed best to reach the organ in view. In the direct electrization one electrode is applied to a selected place on the abdominal wall, and the other electrode is introduced either into the rectum or into the stomach. Both methods are extensively employed by neurologists, and by the specialists for the stomach, as well as by the general practitioners. The application of electricity by these methods presupposes that the current reaches the muscular coat of the stomach or of the intestines, and reaches it in such a strength as to produce a local contraction which is then the cause of a peristaltic movement of either the stomach or the intestines. In the extensive literature on our subject we meet hardly a dissenting voice as to the correctness of this supposition. The statements that the electrization of the abdomen is sometimes followed by defecation; von Ziemsen's† statement of the visible or palpable contraction of the intestines in a hernia during its electrization; the quicker disappearance of water from the stomach or the earlier appearance of the saliv test after the electrization of the stomach; these are the main clinical proofs for the effectiveness of the electrization upon the motor part of the digestive canal. In a case of cancer of the pylorus with visible peristaltic waves of the dilated stomach, Pepper‡ however, reported that the percutaneous electrization of the stomach did not influence its visible peristalsis. Kussmaul,* on the other hand, states that he has seen in one case the visible peristaltic waves on a dilated stomach quickened by the direct (internal) electrization. This seems to speak in favor of the direct and against the percutaneous electrization. Indeed, all writers seem to agree that the direct electrization is preferable to the subcutaneous application. The objection against the former is based mainly upon its inconvenience for the patient; but since the introduction of improved stomach electrodes (Einhorn's§ deglutible electrode; Ewald's‖ modification of it; Wegele's¶ —

* Read before the Association of American Physicians at its tenth annual meeting.
† Von Ziemsen. Die Elektricität in der Medizin, 4. Aufl., 1892.
‡ Pepper. A Case of Scirrhus of the Pylorus, with Remarks on the Electrical Excitation of the Stomach.
* Kussmaul. Archiv für Psychiatrie, Bl. viii.
¶ Wegele. Therapeutische Monatshefte, April, 1895.

spiral electrode) the inconvenience has been considerably reduced. It seems to be in harmony with the general sentiment at present when Ewald thus says: "Surely, by using Einhorn's stomach electrode or my modification of it, contractions of the muscular fibres of the stomach themselves must be obtained." Ewald,* however, says also: "It must, unfortunately, be admitted that all such therapeutic procedures which may be complicated by other factors, do not of themselves prove much until we have the ocular proof of seeing the stomach contract under the influence of the electric current." This "ocular proof of seeing the stomach contract" is, as far as I have been able to see, not yet furnished. The present status is then as follows: It is a generally prevailing view that the percutaneous electrization of the stomach and intestines produces a contraction of these organs; it seems to be universally accepted that stimulation of the mucous membrane of the stomach is the most direct and safest way to effect its contraction. There is no positive proof of either of these assumptions.

While studying the influence of the vagus upon the stomach, I made an unexpected observation which gave rise to a series of experiments upon animals bearing upon the subject of electrification of the stomach and intestines. The results of these experiments I am now going to report.

The electricity in my experiments has reference only to the faradic current. I employed the large sliding "inductorium" of D'Bois-Reymond with more than ten thousand coils: the primary coil was connected with a Grove's cell, freshly arranged for each experiment, while the secondary coil formed with a D'Bois-Reymond key a closed circuit. As is well known, the strength of the current in such an apparatus is measured by the distance between the secondary and primary coils. In my report I shall term it briefly the distance. The current is increased with the shorter distance, but not in exact proportion, the increase of the current occurring more rapidly the nearer the secondary coil comes to the primary. For instance, the increase of the current is greater when the secondary coil is moved from one hundred to ninety than when moved from two hundred to a hundred and ninety millimetres distance.

All the animals were under thorough anaesthesia: chloral for the rabbits and ether for the dogs and cats; in a few cases the animals were also under the influence of curare. Artificial respiration was employed in nearly all the experiments. The results obtained were verified in all the three kinds of animals; the greatest number of experiments, however, were made on dogs, which are best suited for our purpose. The stomach of the rabbit is not a good object for studying the main phenomenon of our results: the stomach of the cat, on the other hand, is rather a good object for study, but this animal succumbs quickly to the influence of ether, and is therefore harder to handle. I am not going to bother you with a detailed account of all my experiments; I shall only report the results which were derived in each case, not from a single but rather from an oft-repeated experiment, giving a uniform effect.

Experiments on the Stomach.—The abdomen of a dog

* Ewald, C. A. Diseases of the Stomach. Translated by Manges, 1892, p. 68.
is opened, the omentum is removed, and the entire stomach is exposed to a full view and kept constantly moist with a physiological saline solution. For local stimulation two copper wires were employed which were conveniently united in a well-polished wooden handle; the wires were flattened at the end and stood about one centimetre apart. By successively stimulating with this double electrode the entire surface of the stomach, it was established that only about one third of it responded with a distinct contraction to an efficient local stimulation. A line drawn perpendicularly from the middle of the cardia to the large curvature divides the stomach into two parts. The part lying to the right of the line is contractible, and the remaining part, or we might say the fundus, is nearly incontractible; a strong and long stimulation produces a hardly perceptible effect. The contractibility of the cardio pyloric part seems to be the better the nearer we come to the pylorus. The change in the contractibility of the two parts occurs quite abruptly. Exactly the same conditions we meet with in the stomach of the rabbit; the very large fundus of this animal is quite incontractible. In cats, however, an efficient stimulation produces a well-marked local contraction in all parts of the stomach, which by the way, does not have a well-developed fundus and is altogether correspondingly smaller than in the other two animals. If there has not been any peristalsis going on before electrization, a local stimulation effects only a local contraction, except in the pylorus, where a stimulation brings on a wavelike contraction of this entire part. If there were peristaltic movements going on in the cardio pyloric part before the stimulation was started, then a local contraction was sometimes the cause of spreading a new peristaltic wave over the contractible area.

If we select a place on the stomach which is capable of giving us a well marked contraction, and then look for the strength of the current which is capable of calling forth such a contraction, we find that the first signs of a contraction become noticeable at a distance of two hundred to a hundred and eighty millimetres, and get more and more pronounced as we are gradually moving forward the secondary coil, until at about a hundred and thirty millimetres distance we obtain the maximum effect. Such a maximal contraction appears like a deep groove on the stomach, which stands parallel to the vertical axis of the organ. The contracted part looks pale and ischemic, and reminds one of an old scar from a burn. If a strong stimulus is used, the latent period is quite short, and the contraction lasts for more than twenty seconds after the stimulation was interrupted. Of course, the numbers mentioned vary to a certain degree; but I do not recall any case where a still shorter distance than a hundred and twenty millimetres was required to obtain a maximal contraction.

After determining such a well-contracting place, an opening was made in the fundus, the contents of the stomach were removed, and the mucous membrane was cleansed with a saline solution. I then introduced the double electrode into the cavity of the stomach, applying its ends to the mucous membrane right opposite the determined place on the outer surface. When I now opened the key while the distance of the secondary coil was still the same as it was when used for the maximal contraction, not the slightest contraction could be noticed even after prolonged stimulation! The immediate stimulation of the outer surface produces the usual contraction—the effect did not suffer by the opening and cleansing of the stomach. As long as the heart continues to beat and the stomach is kept sufficiently moist, the experiment can be repeated again and again with uniformly the same result. The stimulation of the mucous membrane remains without any effect, even when the strength of the current is considerably increased; the secondary coil can be shifted forward to a hundred and ten, to a hundred, or to ninety millimetres distance, or even still nearer to the primary coil, without a sign of a contraction making its appearance. This, however, is not absolute. A very strong current will finally penetrate the stomach wall. At a distance of forty or fifty, sometimes already at eighty or even ninety millimetres the stimulation of the mucous membrane does not fail to produce a well-defined contraction. Usually the current is then exceedingly strong; but even then the effected contraction is in no comparison to those contractions obtained by stimulation of the outer surface with a distance only of a hundred and thirty to a hundred and forty millimetres. In fact, even at zero the contraction produced from the mucous membrane is much weaker than the maximal contraction from the outer surface. The same remarkable difference we find also to exist in the stimulations of both surfaces of the stomachs of the cats and rabbits. The stomach of the latter animal, however, is usually overfilled and very distended; when it is emptied it shrinks considerably and it appears to be in a contracted state. The difference can be clearly seen even then, but the stomach is in this state by no means a good object for our study. Furthermore, I found the difference under discussion to exist also in the stomach of the frog; but this thick walled stomach, with its small and slow contractions, was certainly not a desirable object for an extensive study of our phenomenon. I wish to add that in studying the effect of a stimulation it is necessary to be aware of the accidentally passing by of a peristaltic movement which might be mistaken for a local contraction.

To decide the question whether in electrizing the mucous membrane any current at all is passing through the stomach wall, I made the following experiment: The sciatic nerve of the animal was placed in a Ludwig's nerve electrode, the protruding wires of which were connected by means of flexible conductors with another pair of electrodes. These latter, being only a few millimetres distant from one another, were placed on the outer surface of the stomach, just opposite the space between the electrodes adjusted to the mucous membrane. When, now, the current leading to the latter electrodes was closed the leg of the animal began to jerk. That certainly means that the current passed through the wall of the stomach, and then by the way of the outer electrodes through the sciatic nerve. I made use of this practical arrangement also for some other purposes. For brevity's sake, I shall hereafter refer to this arrangement as the sciatic electrodes. When I
connected the outer electrodes with the uncovered abdominal muscles instead of with the sciatic nerve, the closure of the current did not produce a contraction of these muscles. All this goes to show that a current does pass through the wall of the stomach of sufficient strength to stimulate a motor nerve, but not strong enough to stimulate skeletal muscles, and certainly not strong enough to produce even a minimal contraction of the unstriated muscular tissue of the stomach.

My next line of experiments was to study the effect of electrical stimulation upon the stomach when one electrode was introduced into the stomach and the other applied to its outer surface. For these experiments the animals did not receive any food for two days previous to the experiment. In dogs the stomach was then usually sufficiently empty. The stomach electrode had a thickness of a few millimetres; its connecting wire was hidden within a stomach tube open at the end. It is worth mentioning that after introducing the electrode through the mouth into the stomach, it was always found to be located in the fundus, just outside of the contractible part of the stomach. By bending the wire to the right side I succeeded in placing the protruding point of the electrode into the middle of the contractible area. As an outside electrode I used a metal ball of about fifteen millimetres in diameter attached to a wooden handle. The results of these experiments were uniformly as follows:

When one electrode was introduced through the mouth into the stomach and the other placed on the outer surface of it, about two centimetres or more away from the protruding internal electrode, there was no contraction to be seen even with a strong current; but if both electrodes were placed very near one another, a strong current produced a contraction which was the stronger the nearer both points of the electrodes were to one another. If a piece of omentum, however, was placed between the stomach and the outer electrode, the current produced no effect even when both points of the electrodes stood just over the other. I should add here that the presence of omentum on the stomach did not impair the effect of the stimulation in the case when both electrodes were placed on the outer surface. If the internal electrode was not pressed well against the wall of the stomach, but was suspended within the cavity, which was filled for this purpose with a saline solution, no contraction could be effected, no matter where the outer electrode was placed.

To test still more definitely the value of the direct electricization of the stomach as it is employed clinically, the following experiments were made:

1. The internal electrode was either immersed in the saline solution within the cavity of the stomach or pressed distinctly against the wall of the contractible part of the stomach; this part was then put in such a position as to be easily accessible to the view. The external electrode, the one used before, or a large sponge was placed upon the well-shaved abdominal wall in the nearest neighborhood of the stomach. A strong current produced a strong contraction of the abdominal muscles, while the stomach remained perfectly motionless. This shows that the contraction of the abdominal muscles beneath the outer electrode is by no means a proof the stomach is also contracting. In connection with this I wish to register the observation that by means of the sciatic electrode I could produce the presence of a current in a large area around the external electrode, while the area around the internal electrode, from where the sciatic nerve could be stimulated, was certainly not more than two centimetres in diameter. Against this experiment it could perhaps be said that the direct line between the two electrodes was longer than in the usual direct electrization, and it led perhaps through the incontractible part of the stomach.

2. The wound above the stomach was tightly stitched together, but so as to be able to be opened again in a second or two; the blood at the edges of the wound, which could possibly serve as a direct conductor, was well removed. While the internal electrode was pressing against the front wall of the stomach, the external electrode was put upon the wound, so as to be in the shortest line to the contractible part of the stomach and the internal electrode. A strong current produced a contraction of the abdominal muscles. After interruption of the current the wound was hurriedly opened, the procedure not lasting longer than two seconds; the stomach was then found in the same relaxed condition as before. Whereas we know that a well-defined local contraction of the stomach lasts about twenty seconds after interruption of the stimulation, we must concede that the electrization did not produce a contraction of the stomach. But here again it might be asserted that there was a weak contraction with only a short after-effect which disappeared before the wound could be opened.

3. The electrodes connected with the sciatic electrode were placed upon the stomach just above the internal electrode and covered with omentum; the wound was then well sutured in its entire length, except a small opening at its lower end. The external electrode was then placed on the abdominal wall in the closest proximity to the electrodes on the stomach, and the current was turned on; no motion of the leg, even when the secondary coil was put at zero! This certainly shows unmistakably that when one electrode is placed within the stomach and another electrode placed on the skin just above the stomach, there is on the surface of the stomach, even with the strongest faradization, no current strong enough to stimulate a motor nerve, and certainly not strong enough to produce even a slight contraction of the stomach.

By the last three experimental methods I was enabled to test also the value of the percutaneous faradization of the stomach, and I shall state their results briefly. The corresponding places of the abdomen were shaved and sponge electrodes were applied, one in the back (Erb) and one in the front in the manner soon to be stated. When the stomach was exposed to view and the electrode set upon the skin nearest to the stomach, the abdominal muscles and the muscles in the back were contracting, but not the stomach. When the wound was stitched, an electrode applied on it and stimulated, the abdominal muscles contracted, but a quick reopening of the abdomen did not reveal a trace of contraction of the stomach. When, finally,
the sciatic electrode was applied on the stomach, the wound sutured, and the external electrode placed just above the other electrodes, no current, ever so strong, produced a contraction of the limb.

Thus my experiments demonstrated definitely that neither the percutaneous nor the so-called direct faradization of the stomach was capable of producing a contraction of the stomach, at least in the animals I experimented upon.

The Experiments on the Intestines.—My experiments on the intestines are in most respects a repetition of the experiments upon the stomach, and will be reported briefly.

As is well known, the direct application of both electrodes on the intestines produces a strong constriction of the stimulated part, including a few millimetres outside of each electrode. This local contraction is very rarely the cause of an extended peristalsis. The contraction overlasts the stimulation for fifteen to twenty seconds. The local contraction of the intestines can be effected with a much weaker current than the one required for a well-defined contraction of the stomach. The current which is just sufficient to produce a strong local contraction of the intestines by stimulating their outer surface will produce no contraction by the application of the electrodes to the mucous membrane. This holds good only in dogs. In rabbits I find that an effective current for the outer surface seems to be effective also for the internal surface, except that the contraction is considerably weaker, and even in dogs a slight increase in the intensity of the current will suffice to call forth a contraction by faradization of the mucous membrane. But I can not recall ever having seen one of these contractions being remotely so strong as the ones which can easily be effected by stimulating the outer surface. And there is another difference between the conditions of the intestines and those of the stomach. If one electrode is placed on the outer surface of some part of the intestine and the other electrode is applied to the mucous membrane of even a distant part, there will always be a contraction of the part where the outer electrode rests. Furthermore, the same result will be obtained if the inner electrode is placed in the rectum or in the stomach. On the other hand, the stomach will contract if one electrode is placed upon its outer surface and the other electrode is placed within some parts of the intestines or inserted into the rectum, while it does not contract, as stated above, if this (inner) electrode is placed in the cavity of the stomach itself! If one electrode is placed within the stomach and the other in the rectum, be both cavities cleansed or not, there will be no contraction in any part of the digestive canal. This latter experiment was done already by Schillbach, who reported that he had seen no results from this mode of electrization. Ewald, who distrusts this statement, attributed the negative result to the unclean state of both cavities. Apparently Ewald thought that there was no current at all. This, however, is not so. Even when these cavities are not cleansed an effective current is present, as can be seen by the tetanic contraction of the lower extremities, or by the sciatic electrodes applied to any part of the abdominal viscera lying between the stomach and the rectum, only that the intestines, rectum, and stomach remain motionless. In this respect, however, the result is not altered even by a scrupulous cleansing of the employed cavities.

Concerning the effect of the electrization of the intestines by the application of both electrodes percutaneously, or one electrode in the rectum and the other on the abdominal wall, I will say briefly that the result was exactly the same as in the electrization of the stomach; the intestines remain unaffected by the current. I arrived at this conclusion by the same method which I employed for the test of the value of electrization of the stomach, as described above in full, and which I shall now point out briefly: By ocular observation, by closing and reopening the wound, and by the sciatic electrodes.

I shall add that the results of my experiments represent only the rule and do certainly not exclude the possibility of exceptions—that means that under certain very favorable conditions a current might indeed reach some parts of the abdominal viscera even by percutaneous faradization. As such an exception I am inclined to consider the above-quoted observation of Kussmaul respecting the increase of the peristalsis by electrization, and perhaps the much-quoted case of von Basch is another such exception. Of this latter case I should like to speak here a little more in detail. An emaciated woman, whose thin abdominal wall von Basch was electrizing for a few minutes with a very strong current, fell suddenly into a dangerous faint, from which she recovered after her abdomen was massaged. Von Basch explained this accident by the supposition that the electrization produced hyperaemia of the abdominal viscera, which in turn brought on a cerebral anaemia, and this latter was the cause of the syncope. He adds, however, that the fainting spell could also be explained by a reflex action from the viscera upon the vagi. The case in itself is certainly not a strong one. An emaciated woman can be made to fall in a faint by any sort of unusual instrumental manipulations with her. My interest in this case, however, comes from observations I have made on animals. While electrizing the intestines of a dog, by having one electrode in the rectum and the other on the intestines, I noticed that the intestines became paler and paler, until they were nearly white. Upon examining the heart I found that it had stopped beating. The dog, which was living three minutes before, was dead. Later on I was careful to discontinue the faradization as soon as I noticed that a change in the color of the intestines was taking place. My explanation of this occurrence is that the current struck the splanchnic nerves, and thus produced on the one hand anaemia of the intestines by the stimulation of their vaso-constrictor nerve fibres contained in these nerves, and on the other hand a standstill of the heart by the well-known reflex from the viscera through the splanchnics and sympathetic to the vagi (Goltz's Klopversuch). I also observed that the stimulation of the intestines sometimes effected a standstill of the

† Ewald. Diseases of the Stomach, loc. cit.

respiration, at least in rabbits with natural breathing. This means also an inhibitory reflex action carried by the splanchnics to the respiratory centre (Graham). Now, if the syncope in the case of von Basch was indeed due to the current reaching the intestines, I would then believe that the intestines were not in a state of hyperemia, as von Basch puts it, but rather in a state of anemia, the entire accident being similar to my experience with the dog. Accordingly, we may state that by some exceptionally favorable facilities a current coming from the electrization of the abdominal wall might indeed reach the intestines. But then we should bear in mind that it might occasionally have a fatal effect.

Before concluding, I have to add a few remarks with reference to the electrization of mucous membranes. Faradization of the mucous membrane of the pharynx or of the tongue produces a contraction of the muscles beneath them exactly as if there were no membranes between the muscles and electrodes. In faradization of the mucous membrane of the oesophagus in its upper third the effect is like directly electrizing striated muscle tissue—the contract sets in with the closure and disappears with the opening of the circuit. In the few instances in which I have tried it, I have found that with the internal electrization the circular contraction, and with the external the longitudinal contraction, predominates. On the behavior of the mucous membranes of the stomach and the intestines I have reported above. There is not much difference between the small and the large intestine, but there is a marked difference between them and the rectum; here the mucous membrane is nearly as responsive as the outer surface. There is also in the bladder a pronounced difference between the effects of stimulation of the mucous membrane and those of stimulation of the external surface. In the non-gravid uterus I have not been able to produce any contraction, and a gravid one has not been at my disposal.

The general feature of these experiences is that those mucous membranes which cover striated muscular tissue form no obstacle to the current, and those which cover plain muscular tissue do form an obstacle; within this latter class, again, the tissue which is least irritable is covered with a mucous membrane which offers the greatest resistance to the electrical current. Thus, the muscular coat of the stomach is the least excitable and the mucous membrane offers the greatest resistance. That the difference in the excitability of the muscular tissue is not the only cause for the proved resistance of the mucous membrane of the stomach or intestines can be proved by the following experiment: The mucous membrane of the tongue is replaced by a piece of mucous membrane of the stomach; faradization now does not produce a contraction of the muscles of the tongue. That is also the meaning of the above-quoted experiment—i. e., that electrodes placed upon the outer surface of the stomach could transmit an effective stimulus to skeletal muscles by the way of the motor nerve, but not by direct application of muscular tissue. We can now understand the meaning of some of the apparently paradoxical experiments on the stomach and intestines. The muscular coat of the stomach is less irritable than the coat of the intestines, and the mucous membrane of the stomach offers a greater resistance than that of the intestines. Therefore, if one electrode rests upon the mucous membrane of the intestines and the other upon the muscular coat of the stomach, the latter contracts because the mucous membrane in point has a smaller resistance, or, if one electrode rests upon the mucous membrane of the stomach and the other upon the muscular coat of the intestines, the latter contracts on account of the greater excitability of this muscular tissue. But if one electrode is upon the mucous membrane of the stomach and another rests upon its muscular coat, then there is no contraction, because the muscular tissue in question is the least excitable and the mucous membrane offers the greatest resistance. What the resistance means, what are its nature and extent, I should not attempt to answer for the present; it is reserved for a further study.

The main results of my experiments are, then, briefly stated as follows:

The mucous membrane of the digestive canal offers a considerable resistance to the penetration of the faradical current to the muscular coat; the greatest resistance is found in the mucous membrane of the stomach.

The percutaneous and the direct faradization of the stomach or the intestines can not produce any contraction in these parts.

My statements have reference only to the animals I experimented with. However, abdominal surgery might offer an opportunity to test their validity for the human being.

TAPPING THE VERTEBRAL CANAL.*

By AUGUSTUS CAILLE, M. D.

Having recently seen a case involving the diagnosis between intracranial abscess, parululent meningitis, and tuberculous meningitis, in which case a correct diagnosis was arrived at by means of tapping the vertebral canal in the lumbar region and subjecting the fluid removed to a microscopic examination, I beg leave to report my experience with a method of diagnosis first suggested by Quincke at a meeting of the German Medical Congress in 1891, but one that has apparently received no attention in our country.

Tapping the spinal canal is done with the understanding that there is an open communication between the subarachnoid space surrounding the spinal cord and the ventricles of the brain. The puncture is made between the third and fourth or the fourth and fifth lumbar vertebrae, immediately below the spinous process, a little to one side of the median line, the needle passing between the arches of adjoining vertebrae through the dura into the spinal canal. The terminal cone of the cord is situated at the level of the first lumbar vertebra, and if a puncture is made below this point it is not likely that any of the divergent strands of the cauda equina will be injured. When the

* Communicated, with a demonstration of an anatomical specimen and a brief report of four cases, at a meeting of the American Pediatric Society held in Hot Springs, Virginia, May 28, 1895.
puncture is made the patient's body should be bent forward. In semi-comatose children and in adults narcosis is not required, and aspiration is not necessary, because the liquor cerebro-spinalis will ooze out drop by drop or squirt out if it is under much pressure.

Quincke first tapped in order to relieve pressure symptoms in acute hydrocephalus, and recommended the procedure as a means of distinguishing between serous, purulent, and tubercular meningitis. Von Ziemssen and Lichtlein subsequently reported a number of cases in which tapping had been done. They professed to have found less albumin in brain tumors than in basilar meningitis, also a sugar reaction in brain tumors, but none in meningitis. Pus cocci and tubercle bacilli were positively found. Freyhan, Dennig, Heubner, Senator, Ewald, and others have reported cases. A. Freankel speaks of the disappearance of choked disk after tapping the spine in encephalitis. Führinger, of Berlin, reports eighty-six cases, and in thirty-seven cases of tubercular meningitis, one of which ended in recovery, he professes to have found the tubercle bacillus twenty-seven times. In two cases of hemorrhage into the lateral ventricle blood was found in the spinal fluid. In tubercular meningitis the fluid is invariably clear and limpid; in other forms of meningitis it is cloudy or turbid. One tapping in a case of leptomeninx gave pure pus. In brain tumors, basilar meningitis, and uremia from various causes no improvement was noticeable after tapping. A full report concerning the method will be found in No. 13 of the Berliner klinische Wochenschrift for 1893.

My personal experience is limited to four cases. In the first two cases, in children three and five years of age respectively, suffering from tubercular meningitis, tubercle bacilli were found sparingly in the flaky sediment of the liquor cerebro-spinalis that subsided after standing for twenty-four hours. These cases, however, passed from under my observation, and I am unable to furnish further particulars. They probably terminated in the usual way. The third case is now under my observation in the hospital ward of the Post-graduate Hospital. A child of nine months, with the symptoms of tubercular meningitis, was admitted in convulsions and tapped by me a few days ago. Twenty-five cubic centimetres of a clear and limpid liquid were removed.

My procedure in tapping is as follows: After locating the third and fourth lumbar vertebrae I place the middle finger of my left hand upon the spinous process of the third and the index-finger on the spineous process of the fourth lumbar vertebra, pressing firmly upon the bone. I now mark with the nail of my right index-finger the interspace between the two fixed points and puncture precisely in the median line with a large-sized hypodermic needle attached to its syringe, which is merely used as a handle and not for the purpose of aspirating. No undue force should be used in propelling the needle forward; it readily enters the spinal canal and can be moved about freely if it is in the right place. The syringe may now be unscrewed from the needle, which remains in situ and permits the fluid to escape into a sterilized bottle for subsequent examination. In my last case the liquid oozed out in large drops. Liquor ammonie held to the nostrils of the semi-comatose child increased the flow. After the liquid stopped running it was found that the pupils were equal in size, whereas before the tapping the right pupil had been larger than the left one, with hardly any reaction to light. The spinal fluid was submitted to Dr. Schwytzer, pathologist, for examination, who reports that many tubercle bacilli were found. At the time of this writing the patient remains in about the same condition as before the tapping.

Since reporting these three cases I have tapped once at the German Hospital in a case of acute mania following ether narcosis, in a woman thirty five years old, who now, in the third week of her illness, shows elevation of temperature and symptoms of cortical irritation, particularly choreiform movements of the upper extremities. The patient was tapped without narcosis, sitting in bed in a stooping posture, firmly supported by two nurses. The needle entered the vertebral canal at a depth of four centimetres and was inserted a little to the right of the median line. Fifty cubic centimetres of a very clear liquid were allowed to run out. On minute examination of this fluid, our pathologist, Dr. Schwytzer, found it sterile and containing 0.2% per cent. of sugar. The subsequent history of this case, in detail, will probably be published. In this connection I would emphasize the fact that the patient must not be permitted to make active movements after the needle is in situ, as there is danger of its breaking.

In conclusion, I would express the opinion that tapping the spine may safely be employed to relieve pressure symptoms in various forms of disease. In chronic hydrocephalus it is a safer procedure than tapping the cranium. For diagnostic purposes the value of this procedure is firmly established.

**RESECTION OF THE COLON FOR ADENO-CARCINOMA.**

By W. S. Maclaren, M. D.,
Litchfield, Conn.

Although the chief interest attaching to these specimens is centred in the one which came into my hands a few days ago, successful resections of the intestine so low down as the sigmoid flexure are sufficiently rare to warrant me in going, somewhat in detail, over the history of this case:

I was first called to see this patient on April 13, 1894. I found Mr. C. L., farmer, native born, aged forty-five, who gave the following history:

**Family History.**—Good.

**Previous History.**—Ever since boyhood he has been liable to attacks of colic following any slight indigestion. They have never been severe, have lasted only a few hours, were relieved by pressure, and never have been accompanied by any distension. These attacks have been very frequent, occurring as often as once each month. The colic has never been localized. It never has been accompanied by vomiting, nor by constipation, nor by diarrhoea. His bowels had always been regular, but had

* Read before the Society of Alumni of Bellevue Hospital, May 1, 1895.
acted peculiarly: on going to stool they would move promptly but scantily and without giving any great feeling of relief, and yet no amount of straining could bring away anything further; after waiting five or ten minutes there would be a second small movement which would come without any effort. There was always this double movement of the bowels and occasionally there would be a third.

Present Illness.—Six weeks before my visit he had a severe attack of colic, during which he vomited slightly. There was no distention, and a mild cathartic took speedy effect and relieved all the symptoms.

The whole duration of this attack was about three days. Four weeks later there was a similar attack. He took cathartics freely, but only had a small movement each day. For the two days prior to my visit there had been no movement of the bowels at all, and finally, becoming alarmed, he sent for me. I found him poorly nourished, but with no appearance of cachexia. Temperature, 98.8°; pulse, 84. Abdomen flat. Percussion tympanitic, except over the sigmoid, where there was slight dullness. Palpation did not reveal any tumor. Peristalsis was not constant, but was exaggerated and accompanied by pain and borborygms.

Rectal examination was negative. High enemata brought away small particles of feces, and finally caused a small movement. High enemata were given each day and always secured a small movement. On the fourth day flatus was passed quite freely and pain ceased to be marked. On the tenth day, though small movements were still secured and flatus passed freely, pain was still present and the borborygms persisted. As it was evident that partial obstruction persisted an operation was advised and refused. On May 6th, twenty-three days from my first visit, obstruction became complete, it was not possible to bring away any faecal matter by the enema, flatus ceased to be passed, and the abdomen was slightly distended.

May 7th.—Abdomen more distended. I again urged an operation, and, as pain was becoming very severe, I obtained consent, and with the assistance of Dr. J. L. Buel and Dr. J. T. Sedgwick, of Litchfield, I operated in the usual manner, making a four-inch incision one inch to the left of the median line. On introducing my hand the constricted portion was at once felt and drawn into view. The obstruction was found to be caused by a dense fibrous construction about an eighth of an inch in width. The intestine above and below appeared normal. There were two small hard nodules in the neighboring mesocolon. The whole appearance was so suggestive of malignancy that I decided upon complete removal of the diseased part as the only course open. The shortness of the mesocolon at this point made removal difficult, but by depressing the abdominal wall I was able to get clear of the diseased portion, and removed about three inches of the colon and sigmoid.

I did the ordinary end-to-end operation, using silk sutures. The nodules in the mesocolon were also removed. As there was no leakage from the intestine during the course of the operation, the abdominal cavity was not flushed; but the sutured intestine was irrigated with saline solution and dropped back. Abdomen closed with silk sutures. At the close of the operation the temperature was 100.4°, pulse 120. A soft-rubber rectal tube was inserted its full length and kept in place for a week, at the end of which time the bowels were moved freely by cathartics.

The highest temperature was 101° for a few hours on the second day. At no other time was it higher than 100.4°. It reached normal on the fourth day. The pulse was normal after the third day.

The patient made a good and rapid recovery, gained flesh and strength, and in two months from the operation was working in the hayfield. He never had another attack of colic, and his bowels emptied themselves promptly and naturally. The specimen was examined by Dr. Ferguson, of New York, and found to be adenocarcinoma.

Six months after the operation the patient began to have slight pain over the liver. This soon became more marked, though it did not interfere with his activity. He then began to lose flesh again, gradually became weaker, and finally died just one year after the operation, lacking two weeks. The autopsy was held thirty-six hours after death. The thoracic viscera were normal. The entire liver was indurated and its surface studded with nodules about an inch in diameter and with slightly depressed centres. The convexity of the sigmoid flexure was adherent to the abdominal cecum. There were no other adhesions. The intestinal cecum was not apparently contracted or thickened. There was a large, hard nodule in the mesocolon below the cecum. There was another smaller nodule in the wall of the intestine a short distance from the cecum.

A CASE OF
POSTERIOR SPINAL SCLEROSIS,
WITH UNUSUAL PRODROMAL OCULAR SYMPTOMS.

By C. H. CHUBB, M.D.,
PALVIL, N. Y.

I present the following case on account of the supposed rarity of the eye symptoms, which preceded by at least a year the development of other characteristic features of the disease, and by a much longer period the loss of the knee-jerk and other reflexes:

In March, 1881, I saw Mr. G., aged sixty years, a intelligent business man of good habits and free from syphilitic taint. An uncle was said to have died of cancer of the stomach, and a brother died at the age of sixty of primary cancer of the liver under my care, the diagnosis having been confirmed by an autopsy and microscopic examination. His mother was said to have died of rheumatism, and some form of paralysis "which rendered her helpless."

The symptoms presented were at once strongly suggestive of posterior spinal sclerosis—viz., sharp, lightning-like paroxysmal pains in the lower extremities, together with a sensation of coldness and firm pressure, "as of a stick of wood across the shins;" the patellar reflex was slightly if at all diminished.

Learning that the patient had had some eye troubles for which he had consulted the late Dr. C. B. Agnew, I wrote to the doctor, describing the condition of the patient and inquiring as to the result of his examination. In reply I received a note from his colleague, Dr. David Webster, from which I make the following quotations:

"Examined Mr. G., aged sixty years, on April 22, 1880. Dark spot before left eye for two months; can see sideways. The eye has a central scotoma, about two inches in diameter, at a distance of one foot. Ophthalmoscopic examination shows no lesion that would explain the scotoma. There is a slight erosion of the choroid at the temporal edge of the disc; in the left eye there is a smart pulsation of the vena centralis retina. . . . From the light thrown on the case by your observations I have no doubt that the scotoma was due to disease (sclerosis, perhaps) affecting the optic nerve fibres which supplied the region of the left macula at their origin either in the brain or spinal cord."

It is to be noted that this symptom disappeared in about two months without special treatment, and did not return. The only
other eye symptoms noted were transient double vision and iridoplegia, both of which came on late in the course of the disease.

It is unnecessary to give a detailed account of the case, which extended over a period of fifteen years; suffice it to say that the evidences of the correctness of the diagnosis steadily accumulated—for instance, the loss of the knee-jerk, the straddling gait, extension of the fulminating pains to the upper extremities and to the trunk, girdling sensations at the waist, sensations of pressure at different parts of the trunk, also of cold and heat, sparks of fire, red-hot wires, tingling, numbness, etc., particularly in the arms and hands; also disturbed cardiac rhythm, without evidence of valvular disease. Visceral crises, both bronchial and gastric, were quite pronounced. One of the latter was of a noteworthy character, consisting of the eruption of from one to two quarts daily of a brownish, cloudy fluid, together with a small portion of the insudate, without pain or nausea, continuing for several weeks, then ceasing suddenly. This matter was submitted to Dr. Willard and Mr. Beach, of Catskill, for microscopic examination. They reported the absence of either tubercle bacilli, sarcoma, or other evidence of malignancy, which from the family history there was some reason to suspect.

Extreme inco-ordination developed rapidly in the latter stages, affecting both the upper and lower extremities, the former in even greater degree than the latter. As the patient well expressed it, his limbs were no longer under the control of his will. Toward the last the same condition extended to the bladder and rectum, requiring the use of the catheter to remove residual urine.

At no time did the urine contain albumin, but sugar was temporarily present in small quantities. With the gradual failure of strength, oedema of the ankles appeared, while the fatal issue was hastened by oedema of the lungs. Death occurred at the age of seventy-five years, about fifteen years after the first prodromal eye symptoms were noted. Much to my regret, an autopsy could not be obtained.

The case is a striking piece of evidence of the importance of the eye symptoms in these cases, and of the value of an early ophthalmoscopic examination, even though, as in this case, the information obtained should be of a negative character.

**A CASE OF RICKETS, WITH EXaggerated MOUTH SYMPTOMS.**

**By Henry D. White, M. D., Rutherford, N. J.**

During the past winter the following case came under my notice which displayed symptoms which to me seemed so exaggerated that I thought it might be of interest to others:

The patient was a child eight months old, born of healthy parents. Mother is a nervous, irritable woman, and was unable to nurse the child. When he was about four weeks old he was put upon malted milk, which seemed to agree perfectly. He gained steadily in weight, bowels kept regular, and in every respect the child was the picture of health. One day in moving he gave a sudden cry, which no amount of persuasion would stop, and he continued crying for about three hours. He finally quieted down, but any attempt to move him, and especially his right leg, caused him intense pain. On examining the limb, nothing abnormal was found except extreme sensibility on motion. As it was thought to be only a strain, local applications were used, and after about one week the sensibility began to decrease, but at the same time the gums about the upper incisor teeth began to swell and became very much congested. During all this time his appetite remained good, his bowels regular, but he was more restless than usual. The child had always been in the habit of kicking his legs very much, but it was now noticed that he would not use them at all. He now began to lose a little flesh, and he became pale and the face had an anxious expression. The slightest touch on the gums produced large blood blisters, and they became so enlarged that he could not close his lips over them. After a very careful examination it was finally decided that we had a case of rickets to deal with due no doubt to the lack of animal food. He was at once put on sterilized milk, the modified Meigs's mixture being used. His temperature at this time varied from 100°F to 102°F, with an occasional exacerbation, when it went up as high as 105°F. He was also given cod-liver-oil baths, which, however, had to be discontinued, as they produced a very marked acne. Also given bovine, Valentine's meat juice, the juice from raw beef, and in addition twenty drops of compound syrup of the hypophosphites. For the gums an antiseptic mouth wash containing a considerable amount of sulfocarbonate of zinc.

In three weeks' time after beginning the sterilized milk a marked improvement took place. The temperature dropped to normal and remained there. The pain in the bones decreased, and the gums took on a much healthier condition.

At the present time, which is about two months after the radical change in the diet took place, the gums have gone back to their normal condition, the child has begun to take on flesh rapidly, and there is absolutely no tenderness in the bones.

The thing which struck me so forcibly was the extreme hypertrophy of the gums, which reached such a degree as to entirely cover the teeth and cause quite a marked deformity to the mouth. The symptoms which are usually the most prominent in this disease were either not present or only to a very slight extent. The fontanelle seemed a trifle larger than it should be in a child of his age, but still there was no marked increase in its size, nor was there any increase in the size or change in the shape of the head. There was some sweating of the head, but it was not marked. The rhachitic rosary was only made out on the very closest examination. There was no deformity in any of the bones.

I would also call attention to the very rapid improvement in all the symptoms which took place on the institution of a strictly animal diet.

I have been unable to find anything in any of the reference books which I have been able to obtain that makes very much allusion to the mouth condition present in this case.

The Litchfield County, Connecticut, Medical Association will meet in Norfolk on July 9th, under the presidency of Dr. Frederick H. Wiggin. Papers are expected to be read by Dr. W. H. Welch, of Baltimore; Dr. W. H. Porter and Dr. L. D. Bulkley, of New York; Dr. C. H. Knight, of Lakewell, Conn.; and Dr. M. S. Goodwin, of Thomaston, Conn.

**Attendance on Women in Instrument Shops.**—Women who visit the instrument-makers' shops to be fitted with trusses, elastic stockings, or the like, ought to be able to find a woman in attendance. The W. F. Ford Surgical Instrument Company, of New York, has recently provided such an attendant for its establishment.
THE LUNATIC ASYLUMS OF THE COUNTY OF NEW YORK.

The county of New York—that is to say, the city—contributes about $3,000,000 a year toward the maintenance of the State lunatic hospitals, and in addition supports its own institutions for the care of the insane. The way in which these institutions are managed has been the subject of frequent censure, and this criticism has lately been ratified, so to speak, by the State commissioners in lunacy. In consequence of all this there is an almost unanimous feeling in the community that the care of the city insane ought to be given over to the State. A bill having this as its object was passed by the Legislature at its recent session, but it falls under the head of certain measures which, according to the new State constitution, can not become operative until they have received the approval of the mayor of the city to which they apply, as well as that of the governor of the State, unless enacted a second time by the Legislature. Now the Legislature is no longer in session, the mayor of New York has failed to certify his approval of the bill, and the governor has only until Saturday to give it his approval, even if he had it with the mayor's signature. In the face of this muddled situation the commissioners in lunacy are pressing the governor to put his name to the bill and trust to future legislative action to render it operative. It seems hardly likely, however, that the governor will feel himself warranted in pursuing such a course, and it is doubtful if it would be of any avail if he did; the probability is, therefore, that the city will have to go on for at least another year under the old state of things, paying roundly for what is of no benefit to it, as well as for the continued maintenance of its own discreditable asylums.

The responsibility for this unsatisfactory situation seems to rest upon the mayor, and we can conceive of only one good reason for the part he has taken in the matter, and that is an intention to make the county asylums what they ought to be, coupled with a well-founded conviction of his ability to do so. If this can be accomplished, there is still another requirement that will have to be fulfilled before the great expense incident to the policy can be justified—namely, the establishment of a satisfactory system by which the asylums in question shall be made available for the clinical teaching of psychiatry, a branch of medicine in which the New York medical schools have at present no adequate means of instruction. If this can be remedied, and at the same time the city's pauper insane provided for as well as they could be in the State hospitals, the mayor will deserve the gratitude of the community in spite of the pecuniary burden on the city.

The Appleton Prize, consisting of twenty-five dollars' worth of medical publications, offered annually by the firm of D. Appleton & Co. to the candidate passing the best examination before the board of medical examiners of the State of North Carolina, was won this year by Dr. Lee Cohen, of Baltimore, who had a percentage of 97.57.

The Late Dr. Matthew D. Field.—The Society of Alumni of Bellevue Hospital has adopted the following resolutions:

Whereas, Death has removed our fellow-member, Dr. Matthew D. Field.

Resolved, That the Society of Alumni of Bellevue Hospital have lost a valued and representative member whose devotion and interest did much to advance the society.

Resolved, That we extend to his family our sincere sympathy in their great loss.

Resolved, That a copy of these resolutions be entered on the minutes of the society, and that they be published in the New York medical press.

[Signature] Gorham Bacon.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 2 to June 8, 1895:

ERIKST, Rudolph G., Captain and Assistant Surgeon. So much of the order as directs him to report in person to the commanding officer, Fort Columbus, New York, for duty at that post, is amended to direct him to report for duty at Vancouver Barracks, Washington, relieving Arthur, William H., Captain and Assistant Surgeon. Captain Arthur, on being thus relieved, will report for duty at Fort Columbus, New York.

Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the week ending June 8, 1895:

Biddle, Clement, Passed Assistant Surgeon. Detached from the Naval Hospital, Chelsea, Mass., and ordered to the Naval Station, New London, Conn.

Gardner, J. E., Surgeon. Detached from the Naval Station, New London, Conn., and directed to await orders for sea duty.

Rogers, Franklin, Surgeon. Detached from the U. S. Revenue Steamer Wabash and ordered to the Navy Yard, Boston, Mass.
Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Sixty Days ending May 31, 1895:

HAMILTON, J. B., Surgeon. Granted leave of absence for five days. May 16, 1895.

Stone, G. W., Surgeon. Granted leave of absence for one day. May 22, 1895.

Mead, F. W., Surgeon. To proceed to Portland, Me., and assume command of service. May 18, 1895.

Young, G. B., Passed Assistant Surgeon. Detailed to make physical examination of officers of Revenue Cutter Service. May 24, 1895.

Rosens, M. J., Passed Assistant Surgeon. To proceed to St. Louis, Mo., for special temporary duty. May 17, 1895.

Norman, Stazton, Assistant Surgeon. To rejoin station at Baltimore, Md. May 25, 1895.

Prochezia, Emil, Assistant Surgeon. To proceed to Cleveland, Ohio, for temporary duty. May 25, 1895.

Society Meetings for the Coming Week:

Monday, June 17th: American Laryngological Association (first day—Rochester); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society; Cleveland, Ohio, Society of the Medical Sciences.

Tuesday, June 18th: Colorado State Medical Society (first day—Denver); American Laryngological Association (second day); Ogden (third day); Denver; Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Society of the County of Kings, N. Y.; Baltimore Academy of Medicine.

Wednesday, June 19th: Colorado State Medical Society (second day); American Laryngological Association (third day); Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); Medical Societies of the Counties of Alleghany (annual) and Tompkins (annual—Ithaca), N. Y.; New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

Thursday, June 20th: Minnesota State Medical Society (first day—St. Paul); Colorado State Medical Society (third day); New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

Friday, June 21st: Minnesota State Medical Society (second day); Baltimore Clinical Society; Chicago Gynecological Society.

Saturday, June 22nd: Minnesota State Medical Society (third day); New York Medical and Surgical Society (private).

Harris—Sary.—In New Orleans, on Saturday, May 25th, Mr. Alexander Harris, Jr., and Miss Emile Sary, daughter of Dr. Emile Sary.

Johnson—Gaddis.—In New York, on Thursday, June 6th, Dr. Joseph Lester Johnson and Miss Gaddis.

Kendall—Armstrong.—In Toronto, on Thursday, June 6th, Dr. Charles A. Kendall, of Buffalo, and Miss Edith Armstrong, daughter of Dr. Armstrong, of Toronto.

Newman—Woodward.—In Brooklyn, on Wednesday, June 5th, Dr. Alvah Milton Newman and Miss Georgia Woodward.

Reynolds—Mercer.—In Pittsfield, Mass., on Thursday, June 6th, Mr. Amédée Vallée Reynolds and Miss Charlotte M. Mercer, daughter of Dr. William M. Mercer.

Rose—Zeiller.—In Montgomery, Ala., on Wednesday, June 5th, Dr. E. J. Rose, of Cincinnati, and Miss Juliet Zeiller, of Montgomery.

Saunders—Hardin.—In New Orleans, on Thursday, June 6th, Dr. Dudley Saunders, of Memphis, and Miss Wylidore Hardin.

Died.

Mack.—In Salem, Mass., on Sunday, June 9th, Dr. William R. Mack, aged eighty-one years.

Meeks.—In New York, on Sunday, June 9th, Dr. Edwin J. Meeks, of Stamford, Conn., in the thirty-first year of his age.

Pope.—In New York, on Tuesday, June 11th, Dr. Alexander B. Pope, aged thirty-three years.

Ratgeber.—In New York, on Wednesday, June 5th, Dr. Eugene Albert Ratgeber.

Wallace.—In New York, on Friday, June 7th, Dr. Alphonse M. Wallace.

Wallace.—In New York, on Friday, June 7th, Dr. William B. Wallace.

Letters to the Editor.

The Creosote Treatment of Tuberculosis.

Littleton, N. C., June 5, 1895.

To the Editor of the New York Medical Journal:

Sir: Dr. Conway's article in your issue of June 1st, on Creosote as a Specific in Tuberculosis, calls to mind a case treated two years ago which, with your permission, I will briefly report on account of an unusual occurrence during the course of treatment—viz., deafness:

Mrs. E. B., aged about thirty-two years, family history phthisical. Father, mother, and only sister died of phthisis. Two brothers living who have coughs (presumably phthisical). She consulted me in August, 1892, for troublesome cough. Weight then, one hundred and eighteen pounds. She was a sufferer from chronic bronchitis, an acute attack lighting up on the slightest exposure to cold air. There was also chronic rhinitis, for which she was using some nostrum. The temperature taken morning and evening was 99°-5° and 101° F. respectively. Respiration 20+; pulse 96 to 100. There was partial consolidation of the left upper lobe. The lung had not begun to break down, nor were there any cavities. No examination of sputa made. The treatment was with creosote, one minim, and compound tincture of gentian, a drachm thrice daily, increasing the creosote by one drop every third day until ten minims were taken three times daily. All other treatment suspended. Her appetite was good, and as she had not lost much flesh no tonics were given. Instructions were given to weigh herself twice a week and report. This was continued for some
time, but was finally stopped. The ten-minim dose was taken for nearly two years, with diminution and final disappearance of cough. She has had no attacks of bronchitis. The consolidation resolved. Her appetite has remained good, and she has gained in weight. She weights one hundred and thirty-five pounds now. She considers herself cured. Two months before discontinuing the cresote she noticed her hearing was failing, it being difficult to hear the voices of her friends in ordinary conversation. My attention was finally called to this, and I ordered the cresote stopped. Her hearing was difficult for several months, when gradual improvement was noted, and now, eight months after, it is nearly normal. I was also surprised to note that the catarrh which was so troublesome had disappeared too. Before, she could not sleep on her left side on account of difficulty in breathing through the right nostril. Now she sleeps equally well on either side. Her son, aged twelve years, was given the same dose as herself for the same period, and he became deaf, though on stopping the cresote the improvement was not so rapid as in the first case. In this case the mother, thinking her son would also have the disease, administered it without my knowledge or consent. Physical examination of his chest revealed no indication for cresote.

Searching what literature I have at my command, I fail to find any mention of such a serious occurrence, and I therefore ask those whose experience is greater in this line than mine if such has been observed. No mention of it was made in Dr. Conway's article, although a larger dose was administered and for a greater length of time.

B. Ray Browning, M.D.

943 Madison Avenue, New York, June 3, 1895.

To the Editor of the New York Medical Journal:

Sir:—In the last number of your valuable journal, Dr. John R. Conway, of this city, speaks of four hundred cases of tuberculosis which he treated with "large doses" of cresote. He says that so far he has "not been disappointed in a single case." In reading this article one is struck by the positiveness of the author's statement.

I have been using large doses of cresote since 1887 in the German Poliklinik, where we treat a very poor class of patients of the east side downtown districts; in the Montefiore Home, where the patients are under good sanitary conditions; and in private practice, where they can afford every luxury. But in every class, representing every state of environment, I have been disappointed, not only in a single case, but in many cases. I must, however, state that I do not follow the teachings of Strümpel and Stoerk, who did not obtain good results from using cresote. On the contrary, I still administer it and consider it the best remedy for tuberculosis. But alas! only too often have I been disappointed in using it. How many others have had a similar experience?

Dr. Conway furthermore speaks of "large doses" to be administered, and gives in chronic cases twelve minutes, and in others twenty minutes, three times a day. I cannot call these doses large, especially as Sommerbrot himself used larger doses as long ago as 1891. He gave four grammes a day in chronic cases. This example has been followed by a great many physicians, as cresote is used so very largely and extensively. I, too, have used Sommerbrot's prescription, but found it necessary even to increase his doses. I have given thirty, forty, even sixty drops, three times a day. I have had patients who took eighty and a hundred drops three times a day; yes, one patient took in my office as much as a hundred and sixty drops! (See my article in the Medical Record for April 28, 1892.) She felt, as usual, a little nauseated, but took, as accustomed, a short walk immediately afterward, and felt all right again in a short time. Since then I have not had a similar case, but, as a rule, have found no difficulty in increasing the dose to forty- or fifty-minim doses three times a day. I would recommend this method to every one who uses cresote in his practice. It goes without saying that we must constantly watch the kidneys, etc. (some patients can not take cresote at all). On the other hand, I can only repeat what I said in 1892 (loc. cit.): "It (ecresote) is a substance which mankind can slowly become habituated to, just as arsenic, morphine, alcohol, etc., and the accumulation thereof in the body has—as in all my experience—not been followed by any bad results."

We give cresote only when it is necessary, and in such cases the more the patient can take the better for him.

W. President, M. D.

AMERICAN GYNECOLOGICAL SOCIETY.

Twentieth Annual Meeting, held in Baltimore on Tuesday, Wednesday, and Thursday, May 28, 29, and 30, 1895.

The President, Dr. Matthew D. Maxx, of Buffalo, in the Chair.

Recent Experience in Ureretal Work.—Dr. Howard A. Kelly, of Baltimore, described the renal catheter and its use in the diagnosis and treatment of renal disease. He said that any one at all familiar with urinary diseases could readily call to mind cases of fluid accumulations in the renal pelvis which might have been emptied by the passage of a renal catheter. The instruments which he called renal catheters were fifty centimetres in length, and varied in diameter from one to a half to three millimetres. They were made of silk or of linen, coated with many layers of shellac rubbed down and polished. The catheters intended for immediate use were kept in glass tubes plugged at both ends with cotton. The catheters were sterilized by a 1-1000 solution of bichloride of mercury, and they were kept in an ice-chest for an hour or more before using, in order that they might be sufficiently rigid. After emptying the bladder, a No. 8 or 9 cystoscope was passed in, and the ureteral orifice exposed in the usual way. While this was being done, an assistant caused one end of the renal catheter to protrude from the glass tube, and this end of the instrument was dipped into sterilized boroglyceride. The assistant then held the tube containing the renal catheter over the shoulder of the operator, who seized the end of the catheter and pushed it up through the speculum into the ureteral orifice, and on until a decided sense of resistance was encountered. This indicated that the catheter had touched the upper part of the renal pelvis. It would generally be found that when this point had been reached the instrument had passed in thirty-six centimetres from the external urethral orifice. By covering the outer orifice of the renal catheter with a film of water, the appearance of any urine would be announced by the formation of a bubble at the end of the catheter.

Dr. Kelly then reported several cases illustrating the uses of the renal catheter. The first case reported was that of a woman with an old sinus under the left anterior superior spinous process of the ilium. She had been treated previously for Pott's disease. The renal catheter had shown that there was some obstruction on the left side, for there had been no flow of urine after the catheter had been left in for an hour. Another point noted was that the catheter on the left side did not pass in so far as on the right side by about three or four centimetres.
From these facts it had been concluded that there was complete obstruction of the left ureter in its upper part, and a subsequent operation disclosed an abscess cavity, which was scraped and drained. The patient had made a complete recovery. In another case, one of severe renal colic, there had been found a colon bacillus infection of the pelvis of the left kidney. The introduction of the renal catheter had proved that the other kidney was sound—one of the most important uses of the renal catheter. In still another case considerable pus was discharged as soon as the renal catheter was introduced. Finding it impossible to sterilize the pelvis of the kidney, he had come to the conclusion that there must be some active cause for this, and he had accordingly cut down upon the kidney. This incision had revealed a calculus of about the size of the end of the finger, situated in the lower part of the pelvis of the kidney. The urine had very quickly become clear after this operation.

In conclusion, the author said that he had been able to ascertain exactly the position of strictures in the upper part of the ureter; to test the permeability of such strictures; to relieve the accumulations above such strictures; to diagnosis nephrydrosis; to diagnose cutaneous pyelonephritis; to distinguish between these two latter conditions; to distinguish between soft malignant disease of the kidney and fluid accumulations in its pelvis; to determine the exact nature of an infective pyelitis; and to determine its use in the treatment of renal disease by evacuating any accumulation in the renal pelvis at regular intervals.

The author, in reply to questions from several of the members, said that, with the exception of one case in which he had examined under unsatisfactory conditions in New York, he could say that he had never failed to pass the renal catheter, and that its introduction was usually only a matter of from three to five seconds. The method of introducing it without the speculum he had found to be much more difficult, and it possessed the additional disadvantage of being apt to cause injuries of the mucous membrane, and, as a consequence, ureteral fever.

Dr. Alexander J. C. Skene, of Brooklyn, expressed his amazement and admiration at the great simplicity of the method. His own experience had taught him that unless special precautions were taken, especially in cases where there was unilateral disease of the kidney, or where there was septic material in the bladder at the time of the examination, there was great danger of carrying infection into the ureter. He had endeavored to obviate this in part by carrying in a small catheter and washing out the ureter after the orifice had been exposed.

Dr. J. M. Bally, of Philadelphia, said that with proper light almost any one should be able to catheterize the ureter successfully. Failure was chiefly due to improper illumination.

Dr. Kelly said that the most convenient source of light was an electric lamp placed near the symphysis pubis, so that a broad pencil of light could be thrown by a large head-mirror into the speculum at as small an angle as possible. The ordinary Argand gaslight was not suitable for this work. Daylight could occasionally be employed to advantage. For purposes of drainage, soft catheters about thirty centimetres long, and of the same diameter as the renal catheters would be found useful. To avoid carrying in infectious material, the ureteral orifices should be cleansed with a pledget of cotton moistened with boric-acid solution.

Further Experience and Observations in Hysterectomy for Fibroids.—Dr. S. C. Goumenno, of Portland, Me., read a paper with this title. He said that in the discussion on his former paper on this subject the general sentiment had seemed to be in favor of removing any uterus having fibroids which gave rise to much suffering. The difficulty was to determine just how much suffering would justify surgical interference. The more he did complete hysterectomy, the better satisfied was he with the result. No matter how small a portion of the cervix was left, or how carefully it had been cauterized, there was always risk of leaving scptic material in the cervical canal. In his opinion no uterus could long remain normal if it contained a fibroid. But little more time was consumed in doing a complete hysterectomy than in the partial operation. The chief danger from long operations lay in the amount of blood lost, for most cases of shock were really instances of serious results from haemorrhage. His rule was to operate in all cases as soon as a fibroid was discovered, and he believed that if this rule were adhered to the mortality from complete hysterectomy for fibroids would not exceed three per cent. The size of the fibroid tumor did not by any means determine its capacity for producing suffering and mischief.

For the past twelve years he had used in these operations a continuous suture of catgut, and he had never had occasion to regret its use. The advantages of his method of operating in these cases were: 1. The method was the easiest. 2. By using catgut there was less danger, owing to its elasticity, of strangulating the tissues. 3. With the continuous suture one could always have the blood-vessels under control. 4. If the tissues were fragile from inflammatory action, catgut sutures could be used to almost any extent in the event of annoying bleeding. 5. The absorption of the catgut always took place, so that there was much less danger of fistula. In his experience no complications had followed its use that might not have occurred with any other kind of suture.

(To be concluded.)

Book Notices.

The author begins his preface to the second volume with the words: "I feel that an apology is necessary for the long interval which has elapsed between the issue of the first and of the second volume of this work. The labor, however, has proved much greater than I anticipated on commencing the work, and that involved in the production of the present volume has been particularly arduous."

Delays such as that mentioned are of course to be regretted, and indeed we have sometimes thought there was too much of fractional appearance and too little of the complete in medical publications; but when as a result of delay we obtain a work like the second volume of Hamilton’s Pathology we are almost inclined to recommend its more general adoption, for delay, even if considerable, is a small price to pay for a work so excellent. It is admirable in many ways, and of these not the least is its readableness, for one rather expects a work of this kind and scope to be for reference rather than for continued reading, and yet our reading of it has been a pleasure. Its completeness is more than unusual, and no greater misapprehension can occur than to imagine it merely a work on post-mortem appearances and microscopy, for its matter is anatomical, physiological, and historical as well. Take the consideration of the lungs in Part I, for instance, and first we have fourteen pages
of anatomy and physiology and then eight devoted to the pulmonary signs elicited by auscultation and percussion. The nine pages which follow are devoted to functional diseases of the lungs, and finally we come to diseases of the bronchi. The unusual completeness of the work for one on pathology may be illustrated by the consideration of asthma, for in it we find presented and described all the various theories which concern its mechanism, and these, though not uncommon in medical works, are unusual in pathologies. Tuberculosis is another subject most comprehensively handled, and not only its pathology but its etiology, its relation to other morbid conditions, the causes of death, hemorrhage, and even something of treatment.

The chapters on the kidney are unusually good, and the consideration of functional albuminuria is as good as it is rare in books of this kind. The examination of the urine is excellently treated. The number of these unusual and valuable introductions is very great and we can not begin to enumerate them. For example, how many works on pathology contain discussions on the tongue as an index of disease and on the physiology and chemistry of digestion?

Part II is as good as Part I, and the many pages devoted to the anatomy, topography, and physiology of the brain, in addition to its pathology, are of unusual value. A feature of this part, too, is the pathology of skin diseases, also a consideration of malformations and monstrosities. The diseases due to vegetable and animal parasites are exhaustively considered, and "systematic bacteriology," which is included, is a treatise in itself. The illustrations of the book are very numerous and very good, and the bibliography which is appended to each subject is unusually complete.

As a specimen of book-making, too, the work is very good and the type unusually clear. In short, unusual would rather than any other word express our opinion of Dr. Hamilton's Pathology, provided it were also understood to convey a meaning in the highest degree commendatory.

Text-book of Diseases of the Kidneys and Urinary Organs. By Professor Dr. Paul Fehrenbacher, Director of the Friedrichsbad Hospital, Berlin, etc. Translated from the German with Annotations by W. H. Gilbert, M. D., Physician in Baden-Baden, etc. With Commendatory Letter from Sir Thomas Grainger Stewart, M. D., F. R. S. E., Physician in Ordinary to H. M. the Queen, for Scotland, etc. In Two Volumes. Vol. I. London: H. K. Lewis, 1893. Pp. 194.

This translation pertains to a part only of the author's original work, and includes a consideration of the medical affections of the kidney.

The first portion of the volume gives a brief résumé of the nature and importance of certain prominent symptoms indicated by the quality and quantity of the urine, including albuminuria, haematuria, haemoglobinuria, renal casts, dropy, and uremia. An absence of any comprehensive survey of tests is noted, the author stating in regard to albuminuria that "practitioners should adopt as much as possible the old and reliable procedures of testing for albumin, and should not trouble themselves about small unimportant 'bax,' but should only reckon with decided deposits, which even at first sight show their importance." The author holds that the presence of albumin in the urine is only a single symptom that no more proves renal disease than a systolic murmur at the mitral valve proves organic heart complaint. Albuminuria is divided into five groups: that in healthy individuals with and without special cause; that in different morbid conditions in which the kidneys are healthy, or at least free from evident anatomical lesions; that in febrile complaints; that associated with general and local hyperemia; and that due to actual disease of the kidneys. The various theories that explain the genesis of albuminuria are reviewed; and the author agrees with Saundby and Pavy that medicinal treatment for those forms of albuminuria that do not endanger life is useless.

The subject of haematuria is briefly referred to, while the subjects haemoglobinuria, renal casts, dropy, and uremia receive more extended notice. Uremia is, after reviewing the theories regarding its nature, designated as a collective name, and the author holds that it is futile with our present knowledge to attempt to establish one sole cause as an explanation of all forms.

The section on circulatory disturbances of the kidneys is the first in the second, or special, part of the volume, and considers kidney disease in Asiatic cholera and in pregnancy and the phenomena of engorged kidney and of hemorrhagic renal infarct.

The author classifies inflammation of the kidneys as "diffused" and "circumscript;" the first class being subdivided into acute, chronic without decided atrophy, and chronic with decided atrophy and sclerosis. The various forms of these lesions are described, and the author has taken pains to record the opinions published by different observers in regard to their causation.

The final section of this volume treats of affections of the kidneys that lead to suppuration.

The volume has been carefully prepared by a conscientious student, and, while his opinions may not be generally accepted, they will be fairly considered by both American and English physicians.

The translator has been unfortunate in his work. We note "cystical" for cylindrical, "recrutes" for recruits, "scorbut" for scurvy, "monography" for monograph, "circumscribed" for circumscribed, "alcoholists" for alcoholics, and "eliatr" for clinician. Often the rhetoric is German rather than English, as may be seen in the phrases "more accomplished and precise methods," "much occupied physician," "eliatrers and patholog- logical anatomists have since decenniums," "we reckon diaph- theretic nephritis more distinctly to the desquamative kind," "we are dispensed from the ordinary acceptation." And we are somewhat at a loss to understand what is meant by "incal- lary epithelium" and "anti-albumin drug." As a rule, how- ever, the author's meaning is apparent even if obscure, and the merits of the work are superior to the occasional faults of the translation.

Is this volume the author describes the methods that he has employed in order to attain certain results in operative procedures, his text being that suppuration occurring in a wound made through unbroken skin indicates that the surgeon has committed some avoidable errors in his methods. As he says, it will not do, with our present knowledge and experience, to attribute suppuration after an operation to constitutional de- fects, to bad materials, or to other more or less common ex- cesses, but the surgeon must honestly acknowledge that some error has crept into the manipulations, and search for his fault in order to avoid repeating it. The advantage of a practical acquaintance with bacteriological work is urged, because then the manipulations necessary to keep bacteria out of the wound become automatic.

The classes of wounds, the methods of healing, traumatic favor, septicemia, pyaemia, phlegocytosis, etc., are all described.
The author disinfects the skin by first shaving the surface, then
washing it with soap and Sir Joseph Lister's 1-to-20 solution of
carbolic acid containing a five-hundredth part of corrosive sub-
limate; the surface is then saturated with turpentine, and after
two or three minutes is again washed thoroughly with soap and
the solution by means of a nailbrush. This is done an hour or
wo before the operation, cloths soaked in the solution are
plied over the operation region, and the procedure is repeated
at the time of the operation. Instruments are disinfected by
two or three hours' immersion in a five-per-cent, carbolic-acid
solution; boiling instruments offers no attractions to the au-
thor. He uses towels wet with the five-per-cent, carbolic acid
solution, or 1-to-2,000 corrosive-sublimate solution, and irrigates
the wound with these from time to time as an additional
precaution.

His criticism of the substitution for sponges of gauze-covered
pledgets of absorbent cotton, made by nurses and patients and
imperfectly disinfected, is timely.

The treatment of ulcers and of abscesses form the subjects
of separate sections, and those lesions are thoroughly described.
The book is essentially practical, and, while it departs from
the details of the German school followed in so many American
hospitals, it describes plans of treatment that are likely to com-
mend themselves to the generality of American physicians.

Dose-book and Manual of Prescription-writing. With a List of
the Official Drugs and Preparations, and also many of the
Newer Remedies now frequently Used, with their Doses,
By E. Q. Thornton, M. D., Ph. G., Demonstrator of Thera-
petica, Jefferson Medical College, Philadelphia. Philadel-
phia: W. B. Saunders, 1895. Pp. 5 to 334. [Price, $1.25.] [Saun-
ders's New Aid Series.]

Part I of Dr. Thornton's book deals with weights and
measures and includes the usual matter, as well as a rather un-
usual number of metric equivalents which are most useful.

Part II is devoted to an elucidation of prescription-writing.
The difficulties which attend this task are great indeed, for not
only must solubilities be taught and incompatibilities, as well as
some things chemical, but, worse than all, medical Latin must be
made clear and that, too, not ungenerously. To do these things
interestingly is next to impossible, and the nearest approach to
a readable chapter on prescription-writing we think occurs in
Curtis's General Medical Technology. Compared with this Dr.
Thornton's chapter is dry, but only because Dr. Curtis's was
exceptional. The chapter otherwise is all that could be desired,
and particularly to be commended is the introduction of a list of
abbreviations stated to be imperfect and therefore often dan-
gersous. This list might wisely be studied by many practition-
ers whose habit of abbreviation is not altogether a safe one.

Part III deals with official preparations and forms of pre-
scribing. This portion of the book is very good, and the illus-
trations add not a little to the usefulness of the text, especially
for the benefit of the inexperienced student.

Part IV treats of doses and methods of administration. The
latter are well described and usefully illustrated. Then follow
the official drugs in order, their preparations and doses as well
as the more important of the newer and as yet unofficial reme-
dies. As a dose-book this chapter is excellent.

An appendix includes a number of questions upon the metric
system, with their answers. Though, as we have often said,
we dislike the method of teaching by catechism, yet the impor-
tance of some knowledge of metric measurements and the
widely prevalent ignorance of the subject make the introduc-
tion of these questions a wise one.

The work as a whole is a good one, and we congratulate
Dr. Thornton upon the success with which he has handled a
subject which, though of the greatest importance, is almost
hopeless in its dryness.

The Evolution of the Diseases of Women. By W. Ballis-Head-
ley, M. A., M. D. (Cantab.), F. R. C. P. (Lond.), Lecturer on
Midwifery and the Diseases of Women at the University of
Melbourne, etc. London: Smith, Elder, & Co. Melbourne
[Price, $3.75.]

The author states that the plan of this book is to show the
conditions of the sexual relations as they have been evolved in
the human race, and the position at which they have now
arrived, with their influence on woman; and he aims to trace
these influences through their progressive stages, so far as they
have tended in the direction of disease, and to indicate the
modes of prevention of both the cause and the disease, not only
in the social but also in the medical aspect.

Marriage he considers the normal condition of woman; but
the tendency of man is toward less work and longer periods
of relaxation; his personal leisure and inclination for marriage are
in direct antagonism; he encourages prostitution, and should he
marry he endeavors to limit or prevent progeny. The defi-
ciency of marrying men brings individual women into greater
rivalry, or makes them work for their living; the latter calls for
a high mental education that is at the expense of their bodily
development and sexual strength. In the independent grades
of society woman was never so free, so well cared for and
tended as at present; among the unprovided for and unselect-
ever more hopeless and hard-worked.

The author has examined the statistics of Australasia, and
has found that at the age of twenty and upward twenty-eight
per cent. of the women are unmarried; at thirty and upward,
twelve per cent.; at forty and upward, ten per cent. Statis-
tics prove that an old man's opportunity of marrying a young
wife is rapidly increasing. The birth-rate and the number of
children born to a marriage have decreased in the last twenty
years. Women desire to have children and to perform their
sexual function, but disease induced by delayed marriage may
have rendered this impossible.

The author believes that in the present state of civilization
a large number of women can not marry, that this number will
increase, that there will be an increase in concubinage, in
illegitimate births, and in child-mortality in consequence of
neglect. He holds that it is the duty of the girl who intends to
become a wife and of the wife to her husband, to be healthy.

After considering the influences of civilization on the sexual
relations, the development of the sexual organs of women is
reviewed as a preamble to the discussion of their diseases.

The author adopts Emmet's old views regarding the injuri-
ous effects of laceration of the cervix uteri on the woman's
health.

Anteversion, retroversion, and latero-version and flexion are
said to be due to tight-lacing in many cases, and sometimes to
unsatisfied sexual desire. The latter, while it may be a cause
occasionally, is an unfortunate one to bring into prominence,
for a woman who has suffered from any of these conditions and
learns its cause from her physician, may throw prudence and
self-control to the wind and easily find a means—and would it
always be curative?—to remove that factor in the etiology of
her suffering.

The various morbid conditions of the genitalia of women
are described in an original manner that often indicates that
the author has done his own thinking in solving questions con-
ected with these disorders.

His preference for ether as an anesthetic is to be noted.
The section on treatment is characterized by safe advice as to surgical procedures, and by a brevity and clearness in description that enable the reader to follow the author's methods of operating easily.

The work can be commended as a safe guide for the student of gynaecology.

A Practical Manual of Mental Medicine. By Dr. E. Riol, formerly Chief of Clinique of Mental Diseases, Faculty of Medicine, Paris, etc. With a Preface by M. Benjamin Ball, Clinical Professor of Mental Diseases, Faculty of Medicine, Paris. Second Edition, thoroughly revised and largely rewritten. Authorized Translation by H. M. Bannister, A. M., M. D., Late Senior Assistant Physician, Illinois Eastern Hospital for the Insane, etc. With Introduction by the Author. Utica, N.Y.: Press of the American Journal of Insanity. Pp. xvi-692.

This little volume, written by an alienist, translated by an alienist, and, under the direction of an alienist, printed and bound by the insane, forms a most useful handbook of insanity for the general practitioner. While lacking the exhaustive descriptions, with illustrative cases, of the more extensive treatises on psychiatry, it still presents a clearness of style and excellence of classification which will render it of use to the specialist as well as to the student.

In his definition the author separates mental alienation from insanity in that the latter occurs only in individuals previously sane. The causes of insanity, predisposing and occasional, are treated of in a very thorough manner, and the first section concludes with the description of the individual symptoms of mental aberration.

The chapters which are of particular merit are those treating of the systematized insanities (paranoia) and cerebral neurasthenia. Paranoia is traced through its different stages in a very satisfactory manner. Under cerebral neurasthenia—i.e., nervous excommunication in a degenerate brain—are placed the many diverse forms which have always caused so much difficulty in the classification of psychological medicine. It includes the imperative conception, with all its phobias, folie du doute, the morbid impulses, and obsessions.

The insanities associated with physiological conditions, with local disease, and with general diseases and intoxications are all briefly described.

Altogether, the book can be heartily recommended to any one interested in mental medicine.

The title of this book is almost a review in itself, for a more inclusive title page could hardly be imagined; our duty therefore is rather to criticize than to describe.

The first eighty-four pages are devoted to pharmacal botany, and in it we find a most excellent presentation of the subject, for the matter is ably and clearly written and affords an insight into a study which, though little affected by the medical profession, is none the less useful.

Then follow the articles of the organic materia medica botanically classified, and, as six hundred and twenty-four drugs are considered, it will be seen that the list has not been limited to those which are official. In the case of each drug are presented in order its synonyms, botanical characteristics, habitat, description, constituents, action, uses, and preparations. Then follow the animal drugs treated in the same way.

It has given us much pleasure and satisfaction to read these pages, for we feel that thereby we have made the happy acquaintance of drugs which before had been but name to us. This result is largely due to the great number of illustrations and their admirable character, and, at the same time, due also to the able classification and arrangement of the matter, a classification and arrangement which constitute a clear and succinct and above all an orderly presentation of the subject. It is not our intention to enter into a discussion of the part which medical botany should or should not play in the education of the physician: there are things to be said both for and against it, though the latter are rather the result of necessity than of choice. If one desires knowledge of this kind, however, he can not do better than to obtain Dr. Sayre's book, for in it he will find interest and instruction most plentiful. As for the pharmacists, we feel sure the work will be invaluable to him.

Traité élémentaire de clinique thérapeutique. Par le Dr. Gas-

tron Lyon, chef de clinique médicale à la faculté de méde-

Dr. Lyon's book is useful, not because it differs in any great degree from many other works on applied therapeutics, but because it is ably written and is the most recent presentation of the treatment in use in France to-day. The volume abounds in prescriptions of value, and the practitioner will find it an excellent companion to the familiar works on this subject in our own tongue.

BOOKS, ETC., RECEIVED.

The History of Prostitution. Its Extent, Causes, and Ef-
facts throughout the World. By William W. Sanger, M. D.,
Resident Physician, Blackwell's Island, New York City, etc.
With Numerous Editorial Notes and an Appendix. New

The Female Offender. By Professor Caesar Lombroso and
William Ferrero. With an Introduction by W. Douglas Morri-
son, Her Majesty's Prison, Wandsworth. Illustrated. New

Demon Possession and Allied Themes. Being an Inductive
Study of Phenomena of our own Times. By Rev. John L.
Nevius, D. D., for Forty Years a Missionary to the Chinese.
With an Introduction by Rev. F. F. Ellinwood, D. D., Secre-
tary of the Board of Foreign Missions of the Presbyterian
Church, etc. With an Index, Bibliographical, Biblical, Patho-
jical, and General. New York: Fleming H. Revell Com-
pany, 1895. Pp. x-482. [Price, $1.50.]

From Weakness to Strength. By W. E. Forest, M. D.

Report of the American Humane Association on Vivisection
and Dissection in Schools. 1895.

Annual Reports of the Managers and Officers of the State
Hospitals of New Jersey for the Year ending October 31, 1894.
Campbell-mouth. A Supplementary Report. By Seth
Scott Bishop, M. D., of Chicago. [Reprint from the Journal
of the American Medical Association.]

Le phénol sulfouré dans la tuberculose laryngée. Par

stitution nationale des sourds-muets de Paris, etc. Paris: G.
Masson, 1895. Pp. 5 to 91.

La diphtérie au pavillon d'isolement de l'hôpital Lariboisière, et son traitement par le sérum de Roux. Par le Dr. Gouguenheim, médecin de l'hôpital Lariboisière. [Extrait de l'Années des maladies de la reville, du largay, du nes et du pharynx.]

Improved Double Retractors. By Seth Scott Bishop, M. D. [Reprinted from the Chicago Medical Recorder.]

Grippe, and its Effects on the Nose, the Throat, and the Ear. By Seth Scott Bishop, M. D. [Reprinted from Medicine.]

**Miscellany.**

The Mitchell District, Indiana, Medical Society.—The forty-seventh semi-annual meeting will be held in West Baden, Orange County, on July 5th and 6th, under the presidency of Dr. Joseph Eastman, of Indianapolis. The preliminary programme includes the following titles: Legislative Medicine, by Dr. W. R. Allison, of Peoria, Ill.; The Disastrous Effects following Whitehead's Operation for Plies, and the So-called American Operation, by Dr. Edmund Andrews, of Chicago; A Plea for Surgical Interference in Malignant Growths, by Dr. A. C. Bernays, of St. Louis; Ophthalmia Neonatorum, by Dr. A. Blitz, of Indianapolis; Serotherapy in Surgical Tuberculosis, by Dr. George W. Calo, Jr., of St. Louis; Some Wretched Pelvic Cases, by Dr. A. M. Cartledge, of Louisville; The Use of Electricity in the Treatment of Diseases of the Stomach, by Dr. J. M. G. Carter, of Waukegan, Ill.; Puerperal Eclampsia, by Dr. William M. Catto, of Decatur, Ill.; Litholapaxy, by Dr. Samuel Cochran, of Louisville; A Report of Cases, by Dr. F. M. Coomes, of Louisville; Diseases of the Tongue, and their Treatment, by Dr. Gilbert I. Cullen, of Cincinnati; The Treatment of Corneal Ulcers, by Dr. S. G. Dalney, of Louisville; The Present Status of the Treatment of Stone in the Bladder, by Dr. N. P. Dandridge, of Cincinnati; the President's Address, by Dr. Joseph Eastman, of Indianapolis; Some Points in Connection with Malaria, by Dr. Joseph Eichberg, of Cincinnati; A Report of Cases, by Dr. J. H. Etheridge, of Chicago; The Occult Symptoms of Kidney Diseases, by Dr. T. C. Evans, of Louisville; A Contribution to the Study of Septic Peritonitis, by Dr. Louis Frank, of Louisville; Glaucoma Illustrated by a Series of Cases, by Dr. R. C. Heflebower, of Cincinnati; Some Common Neurological Misseceptions affecting Surgery, by Dr. Frederick J. Hodges, of Anderson; The Vaginal Douch in Obstetrics, by Dr. B. M. Iynes, of St. Louis; Some Peculiarities of the Symptoms in the Recent Epidemic of Typhoid Fever, by Dr. Frederic Keeler, of Cincinnati; Three Hundred Cases of Railway Surgery, by Dr. Webb J. Kelly, of Galion, Ohio; Advances in Infantile Therapeutics, by Dr. J. A. Larrabee, of Louisville; Head Injuries: their Reparative Powers, especially of the Face, by Dr. John E. Link, of Terre Haute; Craniotomy, by Dr. W. H. Link, of Petersberg; What Operations in Rectal Surgery are Unjustifiable? by Dr. Joseph M. Mathews, of Louisville; The Use and Abuse of the Curetta in Gynecologic al Practice, by Dr. L. S. McMurtry, of Louisville; Culpable Neglect in Orthopedic Surgery, by Dr. W. V. Morgan, of Indianapolis; The Mechanism of Nervousness in Young Women, by Dr. Frank P. Norbury, of Jacksonville, Ill.; Intra-uterine Treatment—Means and Methods, by Dr. Chauncey D. Palmer, of Cincinnati; Remarks on the Management of Chronic Prostatitis, by Dr. Allen Pierson, of Spencer; Headaches, by Dr. Curran Pope, of Louisville; Pleurisy, by Dr. A. D. Price, of Harrodsburg, Ky.; Gland Tuberculosis, by Dr. Joseph Ransoholf, of Cincinnati; Intestinal Obstruction, with Cases, by Dr. F. W. Samuels, of Louisville; Lesions of the Upper and Lower Segments of the Nervous System: their Significance and Diagnosis, by Dr. Albert G. Sterne, of Indianapolis; Some Recent Experiences with Gold as a Therapeutic Agent, by Dr. Thomas II. Stocky, of Louisville; When to Em cendate in Traumatic Cycles, by Dr. Richard P. Taylor, of Louisville; Trephining in Epilepsy, with Cases, by Dr. E. W. Walker, of Cincinnati; Vaginal Hysterec tony resection Laparotomy for Pelvic Suppression, by Dr. William II. Wathen, of Louisville; and Typhoid Fever, by Dr. John E. Woodbridge, of Youngstown, Ohio.

The Antidiphtheritic Serum Therapy.—In the Mercerei médical for April 24th there is an article by Dr. Romniciano, of Bucharest, in which he says that the different cases in which these injections have been employed may be divided into the doubtful ones, such as putaneous angina and follicular and stridulous laryngitis, and cases of croup where the patient has been treated with the usual external and internal antiseptic treatment as well as with the injections. Dr. Romniciano has employed these injections in stridulous or spasmodic laryngitis because it presented at the onset so great a resemblance to croup. The following case has come under his observation: The patient, a child six years old, had attacks of hoarse coughing which gradually became more frequent and were accompanied with suffocation and spasmodic inspiration in the same manner as in croup; the respiration was hurried and the inspiration wheezing. The back of the throat showed a slight redness; the skin was hot and dry, and the temperature was 101° F. The author prescribed an injection of serum, but first administered powdered ipecacuanha and a portion of chloroform water, potassium chloride, and benzo-naphthol. The child's neck was wrapped in cotton saturated with a four-per cent. solution of boric acid at a temperature of 104°, and a five-per cent. solution of phenol was kept boiling in the room. Soon after the vomiting, which set in very rapidly, the child was relieved and fell asleep. The cough, however, continued hoarse and frequent. On the following morning the child coughed less frequently and the spasmodic inspiration was not so intense. Auscultation of the lungs revealed some nascent and sibilant roars; the throat, although still red, did not show any trace of diphtheritic false membrane. The tongue was coated and the temperature was 109° F. The treatment was continued, with the addition of eight grains of quinine sulphate. The cough became less frequent and the hoarseness had almost disappeared. In the evening the temperature was 98° F. The patient passed a very good night and in the morning there was no trace of the cough or any spasmodic inspiration or suffocation. An infusion of polygala and sodium benzoate and 64 grains of quinine were given to the child. On the following day, forty eight hours after the injection of serum, the child was taken with frequent bilateral vomiting, and a marked eruption of urticaria appeared on the body. The child urinated frequently, but not abundantly, and the urine was bloody and contained a large quantity of albumin. The temperature was 101° F. The redness over the site of the puncture disappeared soon after the injection and only a small node remained which was scarcely perceptible to the touch. A portion of chloroform water, cocaine hydrochloride, and syrup of ether was administered, also quinine in suppositories, and dry cupping was practised on the lumbar region. The vomiting became less frequent, but the urine was still bloody during the two days that the urticaria persisted. The temperature ranged between 101° F and
Two Cases of Cancer, with Recovery.—In the *Union Medical Journal for May 4th* there is an account of two cases of cancer in which serum therapy was employed. M. Richet and M. Héricourt made an interesting communication to the *Académie des sciences* in regard to this mode of treatment, in which they stated that it could be applied to those affections—such as cancer—for example—of which the microbes had not yet been discovered. The authors made use of an osteosarcoma of the leg, which was first ground and then mixed with water. This liquid was filtered and injected into a donkey and two dogs. The injection was not followed by any reaction, and on the fifth, seventh, and fifteenth days after the injection the serum was taken and used in the treatment of the two patients.

The first case was that of a woman who had been operated upon in 1894 for a tumor which presented the appearance of a fibro-sarcoma, of the size of an orange. It had been growing for eight months and it was adherent to the sixth, seventh, and eighth ribs without invading the skin. In February, 1895, the tumor recurred and at the end of a month was again of the size of an orange. The serum treatment was begun on the 12th of March. Injections of three cubic centimeters were made around the tumor and were continued for forty days, the total amount of serum used being a hundred and twenty cubic centimeters. From the 25th of March the tumor began to diminish perceptibly and this diminution became more and more marked until only a hard patch could be felt, the outline of which was difficult to trace. Furthermore, the patient’s general condition was ameliorated and she had gained flesh in an appreciable manner.

A tumor of a cancerous nature, says the writer, was thus not only ameliorated, but cured, with serum injections when all other treatment, except that with the knife, would unquestionably have been absolutely powerless.

The second case, although remarkable, did not show such decided results. The patient, who had come under M. Reclus’s observation, had a tumor in the lower epigastric region of about the size of an orange, and a diagnosis of cancer of the stomach was made. All surgical intervention having been considered as likely to be ineffectual, the serum treatment was decided upon, and it was begun on the 6th of April with four cubic centimeters of the serum. From this date to the 24th sixty-four cubic centimeters were injected. An amelioration of the patient’s general condition followed; the weight also increased a kilogramme in six days, and in seven days more, two kilogrammes. From the tenth day after the injections were begun the tumor diminished in size, and this diminution became rather rapidly pronounced, so that on the 29th of April the tumor no longer felt separate and prominent. Palpation of the epigastric region gave only a sensation of a resistant surface, of a sort of deep fullness, very vague and difficult to trace.

In the second case, as in the first, the amelioration had been so rapid, so marked, and so indisputable, that, for this reason, might it not be well, he asks, from a prudent point of view, to inquire whether an error had not been made in the diagnosis? However, M. Terrier’s communication with regard to the first case is not without its importance, and, according to the authors, the employment of this serum in a case of cancer has resulted in recovery.

The Relation of Medicine to Cycling.—In the *Medical Chronicle for April* Dr. T. N. Keltnack discusses the relation of medicine to cycling. In health the use of the wheel tells most directly on the heart, producing marked quickening of the pulse, which may continue as long as the cyclist is riding. Few attempts have hitherto been made to study the physical development of persons who have been using the bicycle properly for
years. Dr. G. M. Hammond, of New York, who has examined
a number of cyclists, found in fourteen amateurs who had ridden
from five to thirteen years, traveling from five thousand to
twenty-seven thousand miles, simple cardiac hypertrophy
without dilatation, and a breathing capacity above the average.
A careful examination of fourteen celebrated professional bicy-
clists failed to show any deformity of the spinal column. All
had excessive hypertrophy of the thigh and abdominal muscles,
cardiac hypertrophy without dilatation, and, except in two in-
tances, a lung capacity above the average. Cyclists, however,
are apt to acquire the habit of mouth breathing. In dis-
case the use of the cycle is not necessarily to be proscribed,
In some cases of cardiac dilatation, slight valvular involvement,
and degeneration of the heart muscle, carefully supervised rid-
ing on level surfaces may be very beneficial. Varicose veins
may also sometimes be relieved by properly regulated cycling.
In certain neurotic conditions, especially neurasthenia and hes-
teria, cycling may be productive of benefit, and it is frequently
useful in the treatment of insomnia. Gynecologists have found
cycling advantageous in relieving local pelvic congestion. Care-
fully regulated cycling may be advantageous in certain affec-
tions of the respiratory organs, such as latent phthisis. A cau-
tions and restricted use of the cycle has also proved serviceable
in cases of functional dyspepsia and constipation, goit, diabetes,
and general anemia. Dr. Kelynack gives an impartial sum-
mary of all the evidence that has so far been collected relative
to the evil effects of cycling. Each case must be dealt with in-
dividually, but, as a general rule, the following conditions may
be looked upon as making the exercise inadvisable: Arterio-
sclerosis, tuberculosis, emphysema, extensive valvular disease,
asma, affections of the abdomen and pelvis, obesity, epilepsy,
and chronic affections of the joints and muscles. Fast and
long-distance riding, especially in adolescents, is to be con-
demned. Straining to climb hills or to meet head winds is inju-
sious. Light, judiciously selected meals should be taken at
frequent intervals. The use of alcohol, meat extracts, and such
stimulants as cocoa is to be prohibited. Women should not ride
during menstruation. The clothing should be of wool and
adapted to the easy and unrestrained movements of the rider.
Dr. Kelynack’s article presents one of the fairest statements
of the case for and against cycling that we have seen, and gives
full references to the literature of the subject. We commended
it to the attention of all persons interested in cycling, as well as
to all members of the medical profession.—British Medical
Journal.

The Rhode Island Law Regulating the Practice of
Medicine.—The text of a law that has recently been enacted in
Rhode Island is published in the Atlantic Medical Weekly for
May 29th, as follows:

"Sec. 1.—It shall be the duty of each town and city
clerk to purchase a book of suitable size, to be known as the
Medical Register of each city or town, and to set apart one full
page for the registration of each physician; and when any
physician shall die or remove from the city or town, said clerk
shall make a note of the same at the bottom of the page; and
shall on the first day of January in each year transmit the
office of the State Board of Health a duly certified list of the
physicians of said city or town registered under this law, together
with such other information as is hereinafter required, and per-
form such other duties as are required by this law; and said
clerk shall receive the sum of fifty cents from each physician so
registered, which shall be his full compensation for all the duties
required under this law.

"Sec. 2.—It shall be unlawful for any person to practise
medicine or surgery in any of its branches, within the limits of
this State, who has not exhibited and registered in the city or
town clerk’s office, of the city or town in which he or she res-
dides, his or her authority for so practising medicine as herein
prescribed, together with his or her age, address, place of birth,
and the school or system of medicine to which he or she pro-
poses to belong, and the person so registering shall subscribe
and verify by oath, before such clerk, an affidavit containing
such facts which if willfully false, shall subject the affiant to
conviction and punishment for perjury.

"Sec. 3.—Authority to practise medicine under this law
shall be a certificate from the State Board of Health, and said
board shall upon application issue a certificate to any reputable
physician who is practising, or who desires to begin the prac-
tice of medicine or surgery in this State who possesses any of
the following qualifications:

1. A diploma from a reputable and legally chartered med-
cal college, in the State of Rhode Island, as such shall be
required by the State Board of Health.

2. Satisfactory evidence from the person claiming the
same that such person was regularly and honorably engaged in
the practice of medicine or surgery in this State prior to
January first, one thousand eight hundred and ninety-two.
Any person not qualified as hereinbefore provided, before practising
medicine or surgery in this State shall present himself before
the Board of Health and submit himself to such examination
as said board may require. Said board shall examine any
person presenting himself and if the examination is satisfactory
shall issue its certificate as hereinbefore provided. Provided,
any person so presenting himself shall pay to the board the sum
of ten dollars for each examination, and said fee shall in no case
be returned and shall be applied to the expenses of the
board of health. Applicants may present their credentials by
mail or by proxy, and the board shall issue its certificates to
such applicants as are entitled thereto as though the applicant
were present. All the certificates shall be signed by the presi-
dent and secretary, and attested by seal of the board, and not
more than two dollars shall be charged for any certificate.

"Sec. 4.—Nothing in this law shall be so construed as to
authorize any itinerant doctor to register or to practise medici-
ne in any part of this State.

"Sec. 5.—The State Board of Health may refuse to issue
the certificate provided for in section three of this article, to any
individual guilty of grossly unprofessional conduct of a charac-
ter likely to deceive or defraud the public, and it may after due
notice and hearing, revoke such certificates for like cause.
In all cases of refusal or revocation, the applicant may appeal to
the appellate division of the Supreme Court, who may affirm or
reverse the decision of the board and its decision shall be
final.

"Sec. 6.—Nothing in this law shall be so construed as to
discriminate against any particular school or system of medicine,
or to prohibit women from practising midwifery, or to pro-
hibit gratuitous services in cases of emergency; nor shall this
law apply to commissioned surgeons of the United States army,
navy, or marine-hospital service, or to legally qualified physi-
cians of another State, called to see a particular case, but who
do not open an office or appoint any place in this State where
they may meet patients or receive calls.

"Sec. 7.—It shall be the duty of the State Board of Health
to bring to the attention of the courts any violations of the pro-
visions of the law within their respective jurisdictions.

"Sec. 8.—Any person living in this State, or any person
coming into this State who shall practise medicine or surgery,
or attempt to practise medicine or surgery in any of its branches,
or who shall perform or attempt to perform any surgical opera-
tion for or upon any person within the limits of this State, for
reward or compensation, in violation of the provisions of this
law, shall, upon conviction thereof, be fined fifty dollars, and upon each and every subsequent conviction shall be fined one hundred dollars and imprisoned thirty days, or either or both, in the discretion of the court; and in no case where any provision of this law has been violated shall the person so violating be entitled to receive compensation for services rendered. To open an office for such purpose or to announce to the public in any other way a readiness to practise medicine or surgery in this State shall be to engage in the practice of medicine within the meaning of this law.

"Sec. 9.—This act shall take effect within sixty days of its passage." It was passed on May 14th.

Injections of Salicylic Acid in the Treatment of Uterine Cancers.—The "Providence medica" for May 18th contains an account of this mode of treatment, which has been employed successfully by M. F. A. Patioulisse in seven cases of uterine cancer. The author used a six-per-cent. solution of the acid in alcohol in the following manner: The patients received previously vaginal antiseptic injections from two to three times a day, one of these injections always preceding those of the salicylic acid. From one to four cubic centimetres of the solution were injected into the vaginal portion of the neck of the uterus in five or six places in the affected region. The vaginal portion was then dried and rubbed with tamps of cotton and dusted with iodioform powder, and the vagina was packed with two or three tamps of cotton saturated with a mixture of zylerin and iodioform. The patients were then put in bed and ordered to remain there during the day without moving; in the evening (or the following morning if there was abundant hemorrhage) the tamps were withdrawn and a vaginal injection was given.

The first injections, says the writer, are usually followed by a rather profuse hemorrhage, but the more frequent the injections the less abundant will be the hemorrhage. The places subjected to many punctures give very little blood. In the majority of cases the injections are painful, but the pain disappears very rapidly, and there are no secondary unfavorable symptoms of any kind. The injections are repeated more or less often, according to the gravity of the case and to the intensity of the patient's suffering.

The results of these injections are the almost complete cessation of metrorrhagia, the disappearance of leukorrhrea, the diminution of the pain, the amelioration of the general condition, and the arrest of the progress of the disease.

It will be seen then, says the writer, that the injections of salicylic acid are superior to all other means of treatment proposed for inoperable cancer. If it is true that the amelioration is partly due to the more favorable conditions in which the patients find themselves in the hospital, it cannot be denied that the restorative action of the salicylic acid was prompt in the seven cases observed by the author.

The Hysterical Heart.—We are indebted to the Cincinnati Lancer-Clinic for proof sheets of several important communications read at a meeting of the Obstetrical Society of Cincinnati on December 6, 1894. Among them was the following, by Dr. James T. Whittaker, of Cincinnati:

The heart in hysteria is distinguished by its easy excitability. The increase of action shows itself first after some emotional excitement or after stimulation—tea, coffee, alcohol, etc.—and may amount to a genuine tachycardia, though the frequency rarely reaches above 160 to 120 beats a minute. Retardation is much more rare, though reduction in the frequency of the pulse has been noticed in the so-called sleep attacks—to 45, or even to 40, beats a minute. Real attacks of palpitation are rare, but the patient complains of the feeling of distress, even though the action of the heart is so feeble as to be imperceptible. The pulse is increased after the slightest effort or psychical excitement. Sometimes the mere thought of an effort suffices to excite the pulse. In the rarer cases of retardation the reduction of the force of the heart may lead to syncope. The hysterical sleep attack often shows the condition of apparent death.

Hysterical angina is comparatively rare, though much more frequent than real angina. The condition is recognized by the emotional disturbance which exists during the attack, and which usually evokes an attack, as well as by the absence of organic disease. Patients affected with hysterical angina express great mental distress. They wring the hands, throw themselves upon the bed or sofa, and succeed in exciting everybody about them. The false angina distinguishes itself also by a different situation of the pains, which do not always begin in the neighborhood of the heart, but sometimes in the extremities, or wander about in irregular ways. The attack is associated also with other evidence of hysteria, as by emotional manifestations, erections, discharge of abundant clear urine, etc. Sometimes the attacks may be produced by pressure upon tender hysterogenic surfaces.

Vaso-motor disturbances are frequent in hysteria. Alternating flushing and blanching of the face is very common. There are attacks of sudden coldness of the hands and feet, which may shortly afterward become burning hot. There is often a sensation of numbness in the fingers and toes. Dilatations of the hands, more especially of the fingers, have been frequently noticed. Sometimes the hands are white and the ends of the fingers and nails blue. In some rarer cases the joints only are blue, while the rest of the finger is red, so that the appearance is that of blue rings with crimson borders. The spastic contractions may be so intense as to prevent the escape of blood after puncture. It has been noticed that cups withdraw less blood from hysterical than from healthy subjects. Landouzy records cases in which the stroke of the finger nail or of a pencil would bring out a red line, which might extend itself out to a broad red stripe. Sometimes there develops in the middle of the stripe a pale red hatchlike elevation, so that curious reliefs can be traced upon the skin, in the condition distinguished as autographism. This condition has been observed also in epilepsy, where it does not, however, persist so long. Hysterical autographism may last for years.

In this connection belongs also the condition of vicarious menstruation, with bleeding from the nose, mouth, ear, stomach, etc. Questions of great difficulty in diagnosis often arise in this connection, as hemoptysis and haematemesis are both of especial frequency in young and amenic women. The profession at large is more willing to accept a vicarious hemorrhage from the nose, as epistaxis, as such a common relief of surcharged vessels in congestions about the head. Studies with the changes of blood pressure, which occur in connection with menstruation totally independent of the refinement of the so-called Stevenson's wave, account for the escape of blood from dilated and paretic vessels in unsupported places, and while most cases of hemorrhage from the lungs are really cases of hitherto manifest or latent tuberculosis, there is no doubt that a true hemoptysis may occur as a result of suppressed menstruation. In this connection comes up also the much-disputed question of stigmatization—that is, the occurrence of spots with subsequent hemorrhage in situations which correspond to the wounds of Christ. Many of these cases will not bear investigation, and are readily enough discovered to be frauds; but the recent studies with hypnosis and suggestion have done much to dissipate the incredulity and skepticism of former times. Lowenfeld cites the fact that Facchion was able by suggestion to raise vesicles like those of blisters on the skin. Jeudrassik and Kraft-Ebing produced eschars, and Bouren,
Burort, Berjon, Mabille, and others actually induced hemorrhages. It is therefore not so surprising that certain hysterical patients who have concentrated their minds continuously upon the wounds of Christ should be able to induce hemorrhages in these regions, especially when, as was observed in the case of Louise Lateau, by Bocca, the hemorrhages could be produced mechanically by rubbing with the fingers or with a rough towel.

Hysterical affection of the lungs themselves is much more infrequent, but nervous disturbances in the larynx are among the most common expressions of the disease. Paroxysms of sneezing have been frequently recorded. So-called nervous cough often forms an element of great embarrassment in differential diagnosis. It is usually dry, unattended with expectoration, and has a peculiar bowing character, distinguished as the "sheep cough." It distinguishes itself by its excessive obstinacy. It often appears suddenly and as suddenly disappears under the influence of emotional excitement, and the worst paroxysms can be controlled for the time by diversion of the mind. Severity of the cough eventually produces pain in the chest, and it may produce hemoptysis. Certain hysterical patients learn to draw blood from the mouth, gums, etc., sufficient to tinge the sputum. The writer presented to his class two weeks ago an hysterical patient who expectorated for one entire day a considerable amount of blue sputum, which was supposed to be indigo. Instruction was given, unfortunately in the presence of the patient, to have the next fresh sputum examined chemically and microscopically. This instruction put an end to the discharge.

Aphonia is one of the most common manifestations of hysteria, usually in the form of paralysis of the adductors, whereby it is seen with the laryngoscope that the vocal cords are not approximated in phonation, though the glottis is closed in cough. Curious are those cases in which the patients are unable to speak, but can still sing or express pain. Hysterical aphonia usually supervenes suddenly, and sometimes as suddenly disappears. Varied as are the symptoms of hysteria, they all distinguish themselves by persistence in the individual case. Hysterical aphonia does not differ in this regard. Many cases remain aphonie for years. Where the voice is suddenly restored by artificial means, as by electricity, faith cures, miraculous interventions, etc., the cure, as a rule, is not permanent, but returns when the patient gets away from the impression. Löwenfeld relates the case of a patient whose voice had been reduced to a whisper for years. She was induced to repeat the letters of the alphabet, at first in a low tone, and then louder and louder, without notice having been attracted to the voice. When the patient found that she could articulate the letters distinctly, she began to speak. This was not a simulation, but a loss of will power. The patient was convinced that she was not able to speak, and made no effort to speak. The trial showed the ability without any reference to the will.

Martins reported a case of hysterical aphonia in a servant girl in which the diagnosis was established to a certainty with the laryngoscope. The physician assured the patient that she would be able to utter a loud sound the moment he made pressure upon the larynx. The experiment succeeded, as it always does, perfectly. Under pressure the patient spoke with a loud and distinct voice. As soon as she got home, however, she lost her voice. After repeated experiments of the same kind, he told her she would be able to speak as long as she held her hand at the larynx. This experiment also succeeded perfectly. As soon as she took away her hand she was unable to speak. This condition lasted for weeks, as long as the patient was under observation.

The diagnosis of hysteria as the base upon which symptoms are built is not a matter of the recognition of a disease, but of distinguishing an individual symptom, whether this or that symptom is of hysterical origin or nature. The most essential thing in excluding hysteria is the recognition of the symptoms of organic disease. Most organic diseases have symptoms which hysteria may imitate, but they have also symptoms which hysteria cannot imitate. Thus hysteria may imitate emaciation, cough, pain in the chest, and even the expectoration of blood in tuberculosis. But hysteria can not present the fever, the expectoration, the baseli in the expectoration, and the physical signs of the disease. Then, while hysteria may imitate diseases at the start, it may be easily eliminated in the further course of the malady. Thus hysteria may present at the start the symptoms of an organic disease—myocarditis, valve lesions, etc.—but the conditions are easily separated later (Wagner). Then, certain symptoms belong more definitely to hysteria, such as the paroxysmal attacks, the emotional drams, sensory hemianesthesia, the globus hystericus, etc. These things mark a hysteria. In all cases it must be remembered that hysteria is a real disease of the cortex of the brain.

The Milk Industry in New Jersey.—An article entitled Dairying in its Relations to the Inspection of Milk, by Professor Albert R. Leeds, constitutes a large portion of the Report of the Dairy Commissioner of the State of New Jersey for the Year 1893.

It would be difficult, says Professor Leeds, to overestimate the benefits conferred upon the dairy interests of the State by the work of the milk inspectors under the supervision of the State dairy commissioners since the passage of the first law relating to the adulteration of milk in the year 1880. That law had for its immediate object the prevention of the frauds practiced on the consumer, but it has also resulted indirectly in bringing a great benefit to the dairyman by enforcing improvements in the practical conduct of the dairy.

The watering of milk to such an extent as to bring it below the State standard, which was a fraud mostly practised by the dealers, was so common that, at the outset, the inspectors had their hands full conducting prosecutions. Now it is difficult for the inspectors to find a case. The artificial coloring of milk, which was quite a common practice before 1880, has practically been put an end to by the inspections and subsequent chemical examinations. Much partially skinned milk is still sold in the State as whole milk, and this will continue to be the case until the percentage of fat is regulated by law and fixed at a minimum of 3½ per cent.

But the standard of twelve per cent, of solids is so low that most whole milk can be watered—and much is—with great precision, so as to just escape the penalties of the law.

Though the present law intended to prevent the keeping and feeding of cattle under disease-producing conditions is too general in its provisions to permit of successful prosecutions for its infringement, says the author, yet by the pressure brought to bear by the inspectors, by the wide publicity and popular indignation consequent upon their reports, and the stirring up of the local boards of health to exercise some supervision and care in the issue of licenses, the worst of the evils complained of have been rectified. They will not entirely disappear until more stringent laws and ordinances have been passed and the keeping of dairies in closely inhabited districts is regulated by a proper system of licenses.

But, leaving these dairies, infamous alike in their cruelty to animals, in their brutalizing influences upon men, and in their disease spreading effects upon infants and the general community, the author considers the great benefit of inspection to dairying wherever it is carried on with honest effort. In hundreds of cases the location of the wells and the sources of water
have been examined, and wherever advisable, the purity and suitableness of the water ascertained by analysis. The drainage, ventilation, and sanitation of the yards, outhouses, and buildings have been looked into. The influence of devoted care and watchful supervision of the individual animal in all points referring to its comfort, cleanliness, skillful feeding, proper breeding, etc., have been made manifest in numberless instances, and the rich rewards of this intelligent personal attention to each individual of the herd have been constantly insisted upon. The fixing of the standard at 12 per cent. of solids has done much toward bettering the conditions of milk-production all over the State, but raising the standard to 12-3 per cent., with a minimum 3-5 per cent. of fat, says Professor Leeds, would do a vast deal more. A general improvement in breeding, feeding, and the application of knowledge and skill, now too frequently neglected, would speedily follow.

It is gratifying to learn by Professor Leeds's article of the extent to which the people of the United States are taught how to manage dairies, and that to which the people of France are instructed in the same manner.

Practical investigations in dairying, he says, are carried on at thirty agricultural stations. They include the various processes of butter and cheese making, the losses in these processes and means of eliminating them; the effect of food and of the quality of milk on the composition and yield of dairy products; tests of dairy machinery and apparatus; the utilization of the waste products of the dairy; the management of creameries; and the handling of milk.

In 1825 the Government of France appropriated only 275,000 francs to instruction in agriculture, while at present the amount exceeds four millions. There are three great national schools of practical agriculture and one of the milk industry. The importance of the latter is increased by the very great annual production of milk in France, amounting, according to the most recent statistics, to 1,855,000,000 gallons per annum, and also by the great variety of its cheese and milk products.

The system of public instruction relating to milk is dominated by the national school, which aims to combine experimental and practical work with the largest feasible measure of scientific investigation. This school manufactures on a small scale the different kinds of cheese, butter, sterilized milk, and sugar of milk. It has steam power, refrigerating apparatus, workshops, lecture and museum halls, and an experimental dairy. In the latter about 800 quarts of milk are made each day into butter and cheese.

The course of instruction includes the study of milk, its products, their alterations, the utilization of milk residues, defects and failures of milk and cheese and the means of curing them, also the study of the conduct of dairies, the care of dairy cattle, their feeding, etc.

The great difficulty in France, as it is in this country and elsewhere, says Professor Leeds, is to get the knowledge into the possession of the children of the farm laborers and the sons of the small farm proprietors. These children at the age of twelve or fourteen years leave the common schools, where they have been taught only such elements as all children should acquire, and without further aid would never acquire the special knowledge alluded to above. To overcome this difficulty the system of agricultural instruction in France has recently been widened by the institution of a new class of farm schools. These take lads at the age when they leave the primary schools and while they still have the habit of study, but before they are sufficiently grown to be of great service as farm hands—that is, between the ages of thirteen and seventeen. Their time is divided into two equal parts. Half of the day is devoted to farm work, the care of the cattle, getting their rations ready, the study and care of machines, gardening, tree culture, etc. The other half is devoted to lessons, lectures, laboratory studies, and experiments. The pupils are divided into two sections, each of which takes alternately practical work from the noon of one day to the noon of the following day. While one section is at work the other is engaged in study, and vice versa.

In the United States the number of schools and colleges in which courses of instruction relative to dairying and agriculture are given is not far from seventy. They have about 1,200 instructors, and a total of not far from 12,000 students, of which a little more than one fourth devote themselves especially to agriculture.

In New Jersey, the Agricultural College, at New Brunswick, gives a four-year course which is mainly devoted, under the direction of Professor Vorhees, to the scientific side of the subject, and includes courses in botany, entomology, biology, etc. It also gives a short course of six weeks, which is sufficient for obtaining a practical knowledge of the methods used in creameries, and includes a few of the most important and simple chemical methods, such as determinations of specific gravity, fat, etc. These courses are similar to those given under Professor Caldwell at Cornell University at Ithaca, N. Y., and every one proposing to carry on dairying as a business should avail himself of the shorter course at least. The former college also sends out lecturers to address the boards of agriculture, and has also established extension courses of twelve lectures of one hour each, weekly. After the lecture an hour is devoted to questions and answers and to explanatory addresses. Even three weeks in a model creamery, arranged for teaching purposes, says Professor Leeds, has proved invaluable to many young men now in charge of creameries in New York State and New Jersey. But as they are backward in leaving their homes, Dr. Collier, the director of the New York station (report for 1889, page 537), advocates the establishment of a dairy school in which there should be given instruction only in those technical branches directly relating to the science and practice of dairying, with at least ten branch sections in different parts of the State.

Professor Leeds gives some interesting data as to the milk of different breeds of cows. He says:

"The Holsteins give the lowest solids, then the Holderness, Ayrshire, Devon, Guernsey, and highest, the Jerseys. The order for fat is Holsteins, the lowest, then Holderness, Ayrshire, Devon, Guernsey, and Jerseys. But in total production of milk, the Holsteins lead, with a daily yield of 22-65 pounds, Ayrshire next, then Guernsey, Jersey, Holderness, and the Devons the lowest, with 12-65 pounds."

"In the course of inspection the question of breed frequently comes up and demands the most serious consideration. In the month of April of this year the milk of one of the largest and best-appointed dairies in this State was condemned by the inspectors in the city of New York, to which place it is exclusively shipped, and the dealers were fined. The dairyman thought some serious blunder must have been committed, or that he had been grievously wronged. He had two samples, representing the whole milk of his dairy, analyzed by responsible chemists in New York. They reported that the milk was certainly much below standard."

"Still more astonished at these results, the proprietor of the dairy brought to me two more samples, representing as nearly as possible similar milk to that examined in New York, with the request that I should check the New York results by independent analyses." The samples were analyzed with substantially the results found in New York.

"In order to satisfy myself by personal inspection," Pro-
fessor Leeds continues, "I visited this dairy, where every detail of feeding, care, and the history and condition of the cattle was explained in full. I found the water excellent, and so also the arrangements for cooling and handling the milk. The cows were in admirable condition, and their stable and keeping as they should be. They were mainly thoroughbred registered Holsteins. The analyses above reported are of milk which was stated to be the whole mixed milk of six of these thoroughbred Holsteins in an average condition as to freshness. Their feeding was as follows, April, 1894:

5 a.m.—Hay.
6 a.m.—Four quarts mixed feed; milking.
7:30 a.m.—Hay.
9 a.m.—Turned into field till—
4:30 p.m.—Cornstalks and hay.
5 p.m.—Four quarts feed; milking.
6 p.m.—Hay.

The feed was made up of four tons of ground yellow shelled corn, two tons of middlings, and two tons of bran. I examined samples of these separate materials in the laboratory and found them to be of good quality.

In order to arrive at the nature and extent of the variations in the quantity and composition of these thoroughbred Holstein cattle under the same conditions of feed and keep, but under different conditions as to freshness, I had the total milk of a Holstein, due in the course of about nine weeks, drawn into one pail, and the total milk of another Holstein, which had calved a month previously, drawn into another. The first yielded only a quart and a half. It was stated to be giving about two quarts and a half at the morning milking, or a total of four quarts per diem, and at the time of my visit was the lightest milker in the herd.

The composition of this one quart and a half of milk was:

**SMALLEST MILKER.**

10.24

Taking 12 per cent. as the standard for total solids and 3.5 per cent. for fat, there were, then, in the same herd, fed on the same rations, at one extreme a cow whose milk exceeded the standards of solids and fat by 1.42 per cent. and 1.50 per cent., and at the other extreme a cow whose milk fell below these standards by 1.76 per cent. and 0.70 per cent.

On obtaining these results, the gentleman owning the dairy changed the make-up of the herd, by the addition of a sufficient number of Jersey cattle to insure the percentage of total solids and fat always going above the State requirements.

The author says he is earnestly desirous that nothing stated in his article should be construed as indicating a belief in the inferiority of Holsteins as milk cattle. On the contrary, he says, they are invaluable. The milk obtained by mixing the product from Holsteins with that of breeds giving richer milk he believes to be better adapted to keep and transport in good condition; to obtain a fair compensation from, and better for the general uses of milk (including that of feeding children), than the richer milk obtained from Jersey cattle alone. The drawback that its larger volume is accompanied by a low percentage of solids is in practice readily overcome by mixing. This also is the right way of solving the commercial and legal aspects of the matter.

**The Analgetic Action of Sodium Bicarbonate.—** At a recent meeting of the Société des sciences médicales de Lyon, an account of which is published in the Lyon médical for May 19th, M. Linossier related a number of cases in which he had employed sodium bicarbonate in doses of from eight to thirty grains to allay the pain which occurred a few hours after eating, even when there had been a marked diminution of the excessive hydrochloric-acid secretion. This result had been obtained in patients affected with different diseases—such as biliary lithiasis, gastralgia, neuralgia, and digestive troubles of a mechanical nature. With regard to its action, he said, when this salt was taken into the stomach at a time when digestion was nearly completed it saturated the chyme, excited the muscular coat, and freed the acid which on account of its anaesthetic action might prevent accumulation of gas by relaxing the cardial and pyloric orifices.

The following conclusions, said M. Linossier, might be drawn from these facts: 1. A painful attack occurring when digestion was almost completed, and allayed by the administration of sodium bicarbonate, did not prove that hyperacidity was the cause of the attack. 2. Sodium bicarbonate allayed the painful attacks that occurred periodically after eating, even when there was hyperchlorhydria or diminution of the acidity of the stomach. The analgetic action of the sodium bicarbonate was not lasting; after eight or ten days it ceased to act. Its contraindication was in advanced cases of cancer.

When the sodium bicarbonate failed to act, even in combination with magnesia and bismuth subnitrate, M. Giénard recommended sodium sulphate in doses of from ninety to a hundred and five grains administered in the morning before eating or in the evening. This salt, he said, exercised a remarkable action against the habitual pain in dyspepsia, and thus proved that dyspepsia was not always exclusively gastric, but might depend on the general condition.

**The Treatment of Acute Coryza.—** The Revue internationale de médecine et de chirurgie pratiques for May 25th publishes the following formulas to be used in the treatment of acute coryza: For the purpose of arresting the coryza in the beginning large doses of sodium benzoate (from sixty to ninety grains for children and from ninety to a hundred and fifty grains for adults) are given; painting the mucous membrane with a solution of four grains of cocaine hydrochloride in seventy-five grains of distilled water may also be resorted to. But these means are uncertain in their action and the curative treatment should be employed in the following manner: 1. Inhalation of volatile liquids: Pure carbolic acid, 75 grains; ammonia water, 75 grains; water, 225 grains; alcohol, 150 grains. Several drops of this solution are poured on a linen cloth and the vapor is inhaled. 2. Snuffing powders. The formulas for this purpose are innumerable, but the following are the principal: 1. Cocaine hydrochloride, 2.2 grains; menthol, 1 grain; boric acid, 30 grains; coffee, roasted and ground very fine, 5 grains. 2. Bismuth subnitrate, powdered bennzin, and boric acid, each 90 grains; menthol, 3 grains. 3. Sudol, 15 grains; tannin, 1.5
MISCELLANY.

The Index Medicus.—With the publication of the April number the career of this most valuable journal ceased. In a circular announcing the fact the publisher says:

"Owing to the hard times of 1893 the subscription list of this journal was greatly shrunken, and difficulty was found in making collections from subscribers. The deficit in 1893 was a very material sum, which was largely increased in 1894. Announcement was then made to the medical profession that unless the subscription list of the journal could be placed upon a paying basis I must discontinue its publication. Many friends of the Index Medicus appealed to me to defer action until they could, by individual and organized effort, arrange for an increased number of subscriptions or for a fund whereby its continuance might be assured. After a period of six months it is found that the prospective deficit this year, assuming that all subscriptions are collectible, will be nearly $2,000. Insuch as I cannot afford to carry such a burden I have decided as above announced.""

Irritation of the Neck of the Bladder Due to Large Doses of Sodium Bicarbonate.—At a recent meeting of the Société médicale des hôpitaux, a report of which appears in the Journal des praticiens for May 25th, M. Mathieu reported a case of inflammation of the neck of the bladder in a physician who had taken twenty grains of sodium bicarbonate every day for a month, and twenty-five grains a day for another month. During the second month he had shown symptoms of cystitis. On suppressing the use of the drug these symptoms had disappeared in two days, thus proving, said M. Mathieu, that it was not a case of true cystitis, but of irritation of the neck of the bladder. It was noticed that the urine remained acid during the treatment. M. Haydn remarked that he had never seen large doses of sodium bicarbonate cause excessive acidity of the stomach.

The American Medico-psychological Association.—The fifty-first annual meeting was held in Denver, on June 11th,12th, 13th, and 14th, under the presidency of Dr. Edward Cowles, of Somerville, Mass. The programme included the following papers: The President's Address—The Advancement of Psychiatry, by Dr. Edward Cowles; The Medical Work in the Wards of Hospitals for the Insane, by Dr. P. M. Wise, of Ogdensburg, N. Y.; The Organization of the Medical Work in the St. Peter State Hospital, by Dr. H. A. Tomlinson, of St. Paul, Minn.; Scientific Diets for Hospitals, by Dr. Clarke Gaphen, of Kankakee, Ill.; The New York Hospital and Asylum Dietary, by Dr. Charles W. Pilgrim, of Poughkeepsie, N. Y.; Hospital Diets, by Dr. J. D. Munson, of Traverse City, Mich.; The Care of Inebriety by Specific Treatment, by Dr. B. D. Evans, of Morris Plains, N. J.; The Relations of Alcoholic Indulgence to Insanity, by Dr. G. Alder Blumer, of Utica, N. Y., and Dr. H. M. Banaister, of Chicago; The Histological Pathology of Chronic Alcoholism; Part I. The Experimental Study of the Effects of Alcohol on the Cortex of Rabbits, by Dr. H. J. Berkley, of Baltimore; Pseudo-porencephaly with Remarkable Secondary Degenerations—Demonstration of the Cortex and of the Spinal Cord in General Paresis—Demonstration of the Cortex in Senile Dementia, with Peculiar Changes—Demonstration of Senile Tumors in the Cortex of a General Paralytic, by Dr. Adolf Meyer, of Kankakee, Ill.; Frágilitas Ossium, by Dr. H. C. Egmann, of Cleveland; The State Care and State Maintenance for the Dependent Insane, What it has Accomplished in New York, by Dr. Charles F. MacDonald, of New York; Concealed Delusions, by Dr. B. D. Eastman, of Topeka, Kan.; A Few Canadian Cases in Criminal Courts in which the Plea of Insanity was Presented, by Dr. Daniel Clark, of Toronto; Pelvic Disease and Insanity, by Dr. George H. Rohé, of Baltimore; The Relations of Acenta, Active Cerebral Hyperemia to Insanity, by Dr. Frank P. Norbury, of Jacksonville, Ill.; The Significance of Motor Disturbances in Insanity, by Dr. A. R. Richardson, of Columbus, Ohio; Thyroid Feeding in Certain Forms of Mental Trouble, by Dr. C. K. Clarke, of Kingston, Ont.; The Use of Thyreoid Extract in Insanity, by Dr. E. N. Brush, of Baltimore: A Memorial of Dr. F. T. Fuller, by Dr. P. L. Murphy, of Morganton, N. C.; A Memorial of Dr. E. E. Duquet, by Dr. T. J. W. Burgess, of Montreal; A Memorial of Dr. George C. Palmer, by Dr. C. R. Burr, of Flint, Mich.; and A Memorial of Dr. M. D. Field, by Dr. W. D. Granger, of Bronxville, N. Y.

The Perennial Value of an Old Diploma.—The question as to what becomes of the old diplomas finds a partial answer in the following advertisement, which appeared a short time ago in a Buffalo daily paper:

"For Sale.—A physician's diploma from one of the best colleges in the country. Address Medical News office." A valued correspondent wrote to the address given and received a reply which we now have. From this we learn that the advertiser is a graduate of nearly twenty years' standing from a reputable medical college in this State, a physician in regular practice in a small town not far from Buffalo, a member of his county society, and presumably regarded as a respectable member of the community in which he lives. How his neighbors are deceived, if this is the opinion they hold of him, may be learned from his own words. He writes:

"The diploma in question was issued by the Castleton, Vt., Medical College to my father, who died a few years ago, is on sheepskin, and is in first-class condition. The name and date you can have changed if you wish, but where a man travels away from home it is only customary to change the date, and that is not always done.

"My price for the diploma is $25.

"Of course it is needless for me to say anything about the ease with which money can be made in the practice of medicine if one goes about it rightly. I would advise any one following the line to travel and advertise, staying from two to three weeks in a place. One can make from $25 to $100 a week. If you should wish to see me personally you can come to —— and return home in a few hours."

And this from a physician, the son of a physician, a member in good standing of the Geneseo (N. Y.) County Medical Society! We should advise this man, who respects his father's name as little as he does the honor of his profession, to follow his own counsel and "travel" away from the company of respectable physicians. His letter, which we have in our possession, is at the disposal of the proper authorities who may wish to learn the fate of this particular diploma.—Medical Record.

The Southern Illinois Medical Association.—The twenty-first annual meeting was held in Carbondale on May 5th and 10th. Interesting papers were presented on the following subjects: Insanity, Criminal Responsibility as Related to Insanity, Some Common Forms of Mental Disease, The Diagnosis and Treatment of Typhoid Fever, The Treatment of Inebriates, Malignant Sore Throat, The Physiology of Exercise, and Hemorrhagic Variola. Dr. William R. Mackenzie, of Chester, is the pre-ident, and Dr. J. T. McAnally, of Carbondale, the secretary.

The American Academy of Railway Surgeons is to meet in Chicago on September 23rd, 26th, and 27th.

AN APPARATUS FOR OBTAINING RECORDS OF THE MOTOR FUNCTIONS OF THE HUMAN AND ANIMAL STOMACH ON THE KYMOGRAPHION.
A PRELIMINARY REPORT.

By JOHN C. HEMMETER, Ph. D., M. D., ETC., BALTIMORE.

There have been three methods suggested up to recent times for determining the motor functions of the stomach. Leube's proposition to estimate the duration of digestion—i.e., to determine after a definite average time of six to seven hours after a large meal, or two hours to two hours and a half after Ewald's test-breakfast, whether solid contents were still to be found in the stomach—is subject to too many physiological variations to permit of any reliable deductions. Ewald has proposed the use of salol, which according to Neeki is not changed by acids, but is converted by the alkaline juices of the duodenum (pancreatic and bile) into salicylic acid and phenol. Ewald and Sievers found in fact that salol was not decomposed by acids, but by relatively feeble alkaline fluids. Hence the appearance of salicylic acid, the product of the decomposition of the salicylic acid in the urine, will indicate that the salol has actually passed out of the stomach; naturally, salicylic acid will appear in the urine forty, at most seventy-five, minutes after taking one gramme of salol. Hence delay in its appearance will indicate a retardation in the passage of food into the intestines.

Salicylic acid is recognized in the urine by the violet color produced on the addition of neutral ferric chloride solution. Unfortunately, in this method the time of the decomposition of the salol depends on the occurrence of the neutral or alkaline reaction of the intestine. Even under normal conditions this may vary, since it depends on the changeable reaction of the chyme and the quantity of bile and pancreatic juice which reaches the intestine.

Klemperer has proposed another method for determining the motor activity of the stomach. He pours one hundred cubic centimetres of pure olive oil into the empty stomach, which has previously been washed out if necessary. Two hours later the stomach is aspirated, and whatever oil is left is removed as thoroughly as possible. The difference between the original quantity of oil and that aspirated is used by him as an indication of the motor function of the stomach. Klemperer admits that his method is complicated and objectionable to patients. This, on the face of it, is a valid objection; but when one considers the nature and complexity of the problem to be solved it is no very serious objection, because it is very evident that no method can ever be suggested for determining the motor activity of the stomach which is not complicated and not objectionable to the patient. The entire technique of treating stomach diseases scientifically is objectionable to some patients for the same reasons. These objections, however, will always be overcome by patience and endurance; they are not produced by any real fault in the method, but by hypersensitiveness of the subject to be treated. A method should not be objectionable because of its complexity when from the intricate nature of the problem to be solved complexity is unavoidable; the only test of its usefulness should be its harmlessness and the accuracy of its results.

Dr. Max Einhorn, of New York, has described, in the New York Medical Journal for September 15, 1894, an instrument which records the gastric movements by dots on a narrow piece of paper. No distinction can be made between respiratory and real movements of the stomach by the ingenious piece of apparatus which this talented observer has devised. Nevertheless, Dr. Einhorn's apparatus marks an epoch in the history of the study of the motor function of the stomach; it is the first attempt to obtain a direct record of stomach movements by mechanical means.
The method herein described has been used in a series of experiments on men and animals at the biological laboratory of the Johns Hopkins University. The essential part of the apparatus is a deglutable, elastic, stomach-shaped bag of very thin rubber and attached to an esophageal tube. The stomach-shaped pouch has the shape of the stomach only when it is blown up; it does not occupy much space when it is collapsed, and can be introduced without difficulty into the stomach of patients. The esophageal tube can be very small—not quite half the size of the ordinary tubes used in lavage.

When the bag has reached the stomach, which can be determined by a mark previously made on the tube, it is attached to a double-necked Woulfe flask at E, Fig. 1. The two bottles A and D are used to distend the bag within the stomach. A is elevated above D and full of water, while D is empty. When the stopcock B is opened, water runs from A into D, displaces air in the latter, and forces it into the bag inside of the stomach. When the bag G is in this manner distended, the esophageal tube is closed by the pinchcock E. Now the tube is detached from the Woulfe bottle and connected either with a water manometer or tambour at D, Fig. 2, on the Ludvig kymograph. The slightest contraction of the involuntary fibre of the gastric muscle layer will compress the very elastic intragastric bag and distend the tambour, to which a glass-bulb ink pen is attached, recording the gastric peristalsis as the clockwork moves the paper along. This is the first successful attempt to record graphically the motions of the human stomach on the kymograph. On the upper margin of the kymographion paper, a record pen, connected with a chronometer, indicates seconds on the record by small dots at C, Fig. 2, so that it is possible to determine the time of occurrence and duration of the gastric peristalsis. As the stomach moves passively with every inspiration and expiration, a pneumograph is tied around the patient's waist, recording every respiratory movement on the kymograph. It will be seen on the tracings that many movements of the pen connected with the intragastric bag are passive and caused by the acts of respiration. But there are other very high and long excursions of the gastric pen which are independent of movements of the pneumograph pen, or occur when respiration is suspended for a short while; these are the muscular contractions proper of the stomach. They have been stud-
ied on men and animals. In empty and full stomachs it is possible by this method to study the effect of drugs and electricity on the motor function of the stomach. The Willms Surgical Instrument Company has, according to my design, manufactured an intragastric bag which terminates in an electrode, the wire running up through the esophageal tube to the apparatus, while the tube itself runs to the tambour. Either pole can be made to enter the stomach by the current reverser, while the other pole is placed at the back of the neck or any other desirable place.

It will be easily understood that the apparatus described on Fig. 1 gives an excellent method for measuring the capacity of the stomach, as we can determine exactly how much air is displaced from D, and, noting the quantity which was in the stomach when the patient said the stomach was full, we can permit the bag to be emptied by escape of air, remove the same, and fill it with the same quantity of air outside of the organ as we observed it took to fill the stomach. As this air is in the bag under pressure, the amount of air in the bag does not indicate the exact capacity; to arrive at this, the bag in this way distended must be immersed in a graduated basin full of water to determine the number of cubic centimetres of water it displaces when it is blown up to the size it occupied in the stomach. The stomach capacity may also be arrived at by allowing the air in the bag, when the stomach is distended as far as possible, to escape into a spirometer.

The apparatus is thus also available for the diagnosis of gastrectasia and cicatricial contraction of the stomach. In making studies on the kymograph on the gastric motility, only such patients are taken as have become accustomed to the stomach tube, as the nausea and vomiting first attending the initial introduction of the tube make an exact record impossible. Two gentlemen upon whom I experimented were healthy persons, who became so accustomed to the intragastric bag that they could read a paper while the work went on. This is only a preliminary report, with no pretense to completeness; a more detailed account of the effects of heat, cold, electricity, acids, alcalies, the effects of various kinds of food, and a study of various pathological conditions will, it is hoped, be reported as the work progresses. Above all, I shall endeavor to publish an account of the normal movements, concerning which I have been convinced there are some important new facts to be learned. These normal movements I have studied in men by this apparatus and in animals by placing them in a glass case filled with steam vapor. The abdomen was opened, all bleeding was stopped, thermometers were placed to indicate the temperature of the case, and the gastric peristalsis was studied through the glass. Ether and chloroform and even morphine inhibit the gastric motility, and upon advice of Professor W. H. Howell the animals were rendered insensible by brain compression under a short ether anesthesia, which was later on suspended. As soon as the ether effects wear off the gastric peristalsis is most marked.

On Fig. 4 an intragastric bag is depicted, the object of which is to record the direc-
The slowing of the cardiac impulse, as shown in the gastric record, is not a genuine cardiac inhibition, but only an apparent one, due to the fact that the stomach draws away from the diaphragm and nots during violent contractions and does not receive every impulse; the radial pulse during this period was undisturbed and regular. Distance of secondary from primary coil, four centimetres on the sliding apparatus.

Hemmeter’s triple intragastric bag. Kymographic record of pyloric (No. 1), middle portion (No. 2), and cardiac end of stomach (No. 3), in successive peristalsis.

Naturally, the momentum of the contraction of one bag will be imparted to the other two, but, as the experiment shows on the tracing accompanying the table, this is not so marked as to show on the kymograph. Each bag as a rule records separately, and conjoint action of the three pens, while it does occur, is the exception. The tambours E, F, and G, and their entrance tubes, a, b, c, are made of brass, but the part R is of rubber, like a drumhead, and vibrates continually under the effect of the gastric peristalsis as transmitted from the bag to the tambours. This bag is swallowed in a collapsed condition and blown up afterward within the stomach. It is not free from objections for the reasons mentioned, but for the purpose of recording the origin of the contractions in the human stomach it is the most expedient thing which suggested itself. This apparatus shows that in the human being also the great majority if not all of the peristaltic waves start at the pyloric end. The record of the contraction of the terrapin’s stomach under an induced current, which I am fortunate enough to be able to insert by the kind permission of Dr. George P. Dreyer, shows the latent period of contraction by the record of a Jaquet chronoscope. I can confirm Dr. Dreyer’s observation that it takes strong currents to cause the stomachs of mammals and amphibia, as well as human beings, to contract; no contraction in human beings can be produced before the distance of the secondary coil from the primary is fifteen centimetres, using one element; and that involuntary muscle contracts more readily when the number of stimulations (vibrations) does not exceed twenty per second.

The conviction has been forced upon me that the currents ordinarily used in gastric electrotherapy are too weak, and that the faradic currents are used with an excessively large number of stimulations to the second. It should not be overlooked that the number of stimulations to the second coming from the vibrator may be so far increased that both voluntary and involuntary muscular fibre will not contract at all under its influence.

A CASE OF SUCCESSFUL OPERATION FOR BRAIN TUMOR.

By CHARLES L. DANA, M.D.,
and J. R. CONWAY, M.D.

History, by Dr. Dana.

The following case was so satisfactory from a therapeutic point of view and adds so distinctly to the achievements of cerebral surgery that no excuse is needed for placing it on record. Aside from its importance in giving renewed confidence to the surgeon and neurologist, it has much clinical interest on account of its bearing on the question of the sensory functions of the motor area of the brain cortex.

History of the Case.—Jacksonian Epilepsy; Paralysis of Left Arm, with Sensory Troubles; Headache; Optic Neuritis; Operation, with Improvement of Symptoms.—Charles T., aged sixteen years, was born in Germany. The family history is negative. There is no history of any specific infection or of alcoholic habits. About three years before admission the patient had received a blow on the left side of the head, just over the squamous suture. He was somewhat stunned, but speedily recovered and apparently suffered from no after-effects. About six months later he began to suffer from headache and epileptic convulsions, which latter, so far as I can learn, were general in character. He had, two or three every month for a year. At the end of this time—that is, about a year and a half altogether—he noticed that the attacks began with sensations of tingling and numbness in the left fingers, and that the convulsive movements affected the fingers and arm first. They were followed by unilateral convulsions and unconsciousness. These attacks increased in frequency until he had sometimes one or two a week. About a year ago he noticed that his left arm was becoming weaker and smaller. Five or six months before admission he again suffered from severe pains in the head, and occasionally had attacks of vomiting. He had no trouble with the legs or with the face. The symptoms increased, and he began to suffer from pains in the left arm as well as weakness and stiffness, and sensation of numbness and prickling. When the convulsive attacks came on, he experienced intense pain in the arm before unconsciousness set in. He was first seen by me, May 29, 1894, at my clinic at the Post-graduate School, and at about that time he had had four consecutive fits in one day.

Physical Examination.—The boy seemed to possess a fair degree of intelligence. His gait was normal, and he apparently had no weakness or disturbance of the leg. There was a slight amount of weakness of the muscles of the lower half of the face on the left side. The left arm was very weak, so that he could raise it but a little way from the side, and the grasp of the hand was only about ten on the dynamometer, the normal being forty-five. Detailed examination of the left arm showed weakness of the deltoid, and of the flexors and extensors of the forearm. Supination was nearly impossible, pronation moderately good. Flexion of the fingers and wrist very weak; unable to grasp a pencil or hold a thumb. There was total paralysis of the adductors and abductors of the fingers and of the extensors of the wrist and fingers. Circumference of the left forearm, three inches below the olecranon process, eight inches; right forearm, nine inches. There was exaggeration of the tendon reflexes of the arm, and every now and then clonic movements of the flexors and extensors of the fingers and also of the flexors of the forearm took place. Slight irritation of the finger-tips would cause a sharp, painful contraction of the forearm and hand. The left arm was colder and redder than the right.

Sensation.—The sense of contact over the left hand and arm is slightly diminished; he is unable to locate the point of contact within two or three inches. Two points, two centimetres apart, on the finger-tips are felt as one. Localization by placing the fingers of the normal hand on a definite point on the paralyzed hand is defective; but he localizes better an object on the right hand with his left finger than on the left hand with his right finger. Pain sense, if anything, slightly overactive; a pinch or a prick of the left hand causes more pain than on the corresponding part on the right hand. He suffers from neuralgic pains in the left arm. Temperature sense normal to both heat and cold. Muscular sense is defective; he does not recognize the position of the fingers or hand or arm well, and he does not recognize weights well. The most striking defects, therefore, are the impaired muscular sense and the impaired localization sense, together with a little hyperalgesia and excessive reflex excitability. The left leg shows slight increase in the knee-jerk, but no ankle-clonus and no particular motor weakness, nor is there any sensory trouble. There is very little motor trouble in the face and no sensory disturbance. The right half of the body is normal.

The patient complains a great deal of intense frontal headaches, which, he says, are worse at night and in the early morning. Examination of the eye shows a well-marked optic neuritis on both sides; the visual acuity, however, is still good, though there is some limitation of the visual field. Hearing, smell, and taste are normal. The bodily functions, aside from those described, are normal; the appetite is good; the bowels are regular.

The patient, as may be seen, presented in a typical manner the general symptoms of a brain tumor and also well-marked localizing symptoms. Owing to the fact that the left arm was paralyzed and that sensory disturbances were present here, and that the face and leg were but little affected, it was easy to say that the lesion was affecting the arm centre of the right cerebral hemisphere. The fact that the pain and paraesthesia and initial convulsive movements began in the fingers indicated that the finger and hand centres were more particularly involved. The diagnosis of a tumor involving the arm and hand centres was therefore made. Owing to the fact that the boy had had convulsions and headache before any localized symptoms appeared, it seemed possible that the tumor might be anterior to the motor centres and might be invading them secondarily.

The age of the boy, the absence of syphilis and of any signs of tuberculosis, together with the rather rapid growth, led me to think that the tumor was probably a glioma or gliosarcoma. The case was turned over to Dr. Conway, assistant surgeon to the Fourth Medical Division at Bellevue Hospital, who kindly consented to operate. The patient was also seen by Dr. Herman M. Biggs, who confirmed the local diagnosis and suggested the probability that it was a gliosarcomatous tumor. Dr. Conway operated on the patient June 4th. The details of the operation I do not purpose to give here, but leave them to be described by him.

The Operation, by Dr. Conway.

On the day previous to the operation the scalp was thoroughly shaved and cleansed, the bowels were purged, and the patient was carefully nourished. At this time Dr. Dana
mapped out the hand and arm centres, leaving an indelible mark with the silver-nitrate pencil.

Two hours before beginning proceedings five minutes each of tincture of strychnine and tincture of digitalis with a fortieth of a grain of strychnine sulphate were administered, because the pulse was somewhat feeble and the operation likely to be severe and prolonged.

*June 14th.*—The patient being etherized and the usual antiseptic precautions taken, a horseshoe-shaped incision was made, including an area about three inches in diameter, the base of the semicircle being below upon the right side of the head, and the centre of the flap corresponding to the motor area previously marked out. The scalp was carried firmly to the bone, incising the periosteum at the same time, the latter being turned down adherent to the scalp, thus exposing the bone at once. A conical trephine three quarters of an inch in diameter was applied to the skull over the arm centre, and after a great deal of difficulty, because of the extreme thickness of the bone, an opening was made. In removing the button of bone it was found that the dura was adherent, causing it to be slightly torn. The trephine was again applied above and a little posteriorly to the first opening and all the bone between and around was cut away with the rongeur forceps until the aperture in the skull measured nearly two inches in diameter. This was done because it was evident from the appearance of the dura that the tumor was extensive and would require a large opening. A T-shaped incision was then made in the dura over the centre of the tumor, which was found closely adherent to it, the pia and brain tissue being somewhat torn in separating the two from the dura. The tumor, which was found to be a flat, tough, and fibrous mass in appearance, about an eighth of an inch in thickness, was then separated from the pia and brain substance by means of the handle of a silver teaspoon. The new growth was so incorporated with the gray matter of the brain substance at about the centre of the first trephine opening that a small portion of brain substance was removed with it, and for a short space around this centre small deposits of the same substance, in a number of minute spots, were noticed, but not interfered with.

By exploration anteriorly, it was found that the growth extended probably some distance beyond the opening in the bone already made, but, as the portion already removed was two and a quarter by two inches and the patient was rapidly growing weak, it was thought advisable to allow any remnant to remain and be removed by a later operation.

All portions of the main growth posteriorly, above, and below having been thoroughly taken away, the edges of the incised dura were brought together with catgut and the scalp was stitched with interrupted silk sutures, drainage being provided for by means of very small rubber tubes.

It was immediately found necessary to stimulate him freely with the customary heart tonics, used hypodermically, until the heart became safely strong.

Three hours after the operation he had a general convulsion, and during the same night three more followed, but none of them were of a very severe type.

The wound remained aseptic and rapidly healed, all sutures and drainage-tubes having been removed within five days. The temperature was elevated two degrees during the first week, but gradually became normal.

**History continued, by Dr. Dana.**

The arm and hand centres were mapped out upon the shaved scalp by myself, the skull was trephined, the dura opened, and a tumor found immediately under the point of the first trephine opening. The opening was enlarged extensively, and it was found that the growth lay directly beneath the dura mater, from which it had apparently started, and extended forward a considerable distance, being bounded anteriorly by about the middle of the frontal lobe, posteriorly it reached as far as the posterior edge of the first central convolution, and below it extended down to near the lower edge of the central convolutions. The tumor was in its posterior part, where it covered the central convolutions, easily stripped off from the pia mater; but beneath this area—that is to say, directly over the middle portion of the central convolutions—the cortex was seen to be congested, dark, and infiltrated with grayish spots. While not entirely destroyed, its functional activity was evidently impaired, for it did not respond to strong irritation of the faradie current applied directly upon the convolution. On stripping the tumor up anteriorly it was found that about the base of the second frontal convolution the tumor had become attached to and infiltrated into the cortex so that this was torn in removing parts of it. As much as possible of the tumor was removed, but a considerable portion of the anterior part had to be left, although the opening in the skull was enlarged as much as was thought safe. The patient made a good recovery, the wound healing by first intention; but in the first day he had two convulsions and during the following fortnight he suffered intensely from headaches, pain in the arm, and he was at times acutely delirious. The symptoms gradually abated, and by June 27th his mind was clear, his head was free from pain, and he felt thoroughly convalescent.

Physical examination at that time showed the following conditions: The paralys of the face was unchanged and the condition of the leg seemed the same. The left arm could be moved more freely; the patient raised it from his side, flexed and extended it with greater readiness; there was less rigidity, and the reflex excitability and tendency to twitching had entirely gone. There was still considerable weakness in extension and flexion, and pronation was very feeble. The fingers were held most of the time in extension, but they could be flexed feebly; they could also be slightly adducted and abducted, so that on
the whole the movements of the arm were better than before
the operation.

Sensation.—The pain in the arm had disappeared, and there
was hardly any of the hyperalgesia which he had before ex-
erienced. Still hyperalgesia did exist, as shown by simulta-
neous pricks of the two sides or by pinches of the two forefingers,
the boy always saying that he felt more pain when the skin of
the left hand was pinched than when that of the right was so

Light contact by touch of the finger or the head of a pin
was appreciated normally, or almost so. There was a slight
delay in contact sensation, however. Localization was slightly
more defective than previous to the operation. A point on
the thumb would be felt on the forefinger; two points, two centi-
metres apart, would be felt as one. Motor touch, so called,
as shown by his attempts to describe an object placed in his
hand, was defective, though not much so; he thought that a
quarter of a dollar was a half dollar, and was rather doubtful
of the nature of the coin altogether. Temperature sense was
normal.

The muscular sense, as shown by appreciation of movements
of the fingers and position of the fingers, hand, and forearm,
was quite defective. The fingers when held out straight were
said to be flexed, and attempts to place the right arm in the
same position as that in which the left was placed were unsuc-
cessful. Appreciation of weights was also defective, and at-
ttempts to use the hand in any way were extremely awkward,
though this was largely due to the stiffness and weakness of the
limb.

April 2, 1895 (eleven months after the operation).—The pa-
tient went until July, 1894, without further convulsions. Since
that time he has had about one convolution a month. The sei-
zure, however, are now unilateral only, and not accompanied
with loss of consciousness, as was the case before the operation.
They are preceded by an aura of tingling and slight pain begin-
inning in the fingers and running up the arm. The hand and
arm go through clonic movements, the face and leg twitch
slightly, the eyes turn to the left, and the leg is very slightly
moved.

The paralysis is now less than before the operation. The
boy can raise the arm straight above the head, flex and extend
it, flex the fingers, especially in the ulnar distribution, and ex-
tend the fingers slightly, but not the wrist. He can pronate
but not supinate. The fingers are kept in rather rigid flexion,
and they are straightened with some difficulty. There is clonus
on forced extension of the arm and hand.

The arm and hand go through clonic movements, the face and leg twitch slightly, the eyes turn to the left, and the leg is very slightly

There is no pain or tenderness now in the affected side, nor
is there any sensory disturbance in the face or leg.

The hand shows defective localizing sense. When a point
or the finger is touched, he in the majority of cases refers it to
the wrong finger, and he can not touch a given point on the
affected hand with the fingers of the normal hand.

The sense of position of the fingers and hand, the tactile,
pain, and temperature senses are normal or nearly so. He has
no headaches; his eyesight is good, and there are only slight
traces of the optic neuritis. His general health is good.

The piece of tumor removed was found to be from a spinello-
celled sarcoma.

The Death of M. Verneuil, the distinguished French sur-
geon, is announced as having taken place on Wednesday, the
12th inst.

RESECTION OF THE FEMUR
FOR DEFORMED UNION OF FRACTURE.

BY JUAN JOSE MARTINEZ, M. D.,
SURGEON TO THE HOSPITAL DE SAN JUAN DE DIOS, GRANADA, NICARAGUA.

I take the liberty of calling the attention of the profes-
sion to this case not merely with the view of bringing it to
their notice, but because of some observations connected
with it which may result in important consequences if in-
vestigations are carried further by expert men.

The case is that of R. V., aged twenty-seven years, of Costa
Rica, who received a gunshot wound in the upper part of the
thigh, fracturing the femur at the junction of its upper with the
middle third, at the battle of Limon, in Masaya, during the
Nicaraguan revolution of 1893.

I was chief surgeon of the expeditionary force in that city,
and as the patient came to me I applied a provisional dressing
and splint, and sent him next day to the General Military Hos-
pital in Granada. Owing to the great number of wounded and
the limited number of good surgeons, this patient happened to
fall into the hands of an inferior one, who left him in the con-
dition represented by Fig. 1. Eighteen months afterward the
poor man consulted me, and I advised an operation.

An incision four inches and a half in length was made over
the most prominent part, and this discovered a large and very
rough mass formed of superabundant callus, soft at some points
and very hard at others. The periosteum was retracted, a piece
of bone as large as half of a large apple was chiseled out, and
a wedge-shaped piece of bone removed; then the femur was
fractured, bringing it to the proper line. The periosteum was

Fig. 1. Before the operation.  Fig. 2.—After the operation.

replaced, and the wound packed with iodoform gauze. Plenty
of hot water was the only wash used in the operation; the in-
struments also were put into boiling water.
I then applied a back and two side splints, the outer one with a window, to allow of dressing the wound; also applied extension and counter-extension. The splints were covered with rubber cloth to prevent the cotton of the splints from becoming soaked with the discharges or with the washing.

I consider this a very important precaution in the tropics, where decomposition goes on so rapidly that a few drops of pus soaked into the cotton of the splints will in a very few days develop worms. For this reason I also use alcohol in the treatment of wounds, and by means of a syringe I throw the alcohol in between the splints and the skin, with the object of evaporating the moisture that there may be, and avoiding thereby the formation of worms and also of bedsores.

A surgeon who has not practised in the tropics cannot form an idea of the rapidity with which worms are developed in all cases where a limb has to be incised for many days, and where the immobility of the splints is absolutely necessary, as in fractures.

During the last four years I have used this method of applying splints in severe cases of compound fractures of the limbs, together with the alcohol treatment of the wound, with excellent results. In these cases I have seen very little inflammation, not so much suppuration as is usual in this class of cases, and very little fever.

Hippocrates, Paracelsus, and others employed wine as a dressing to wounds, and they did so under the impression that it dried the part, and with the belief that a dry condition was nearer a state of health, while humidity was nearer that of disease. Their followers used wine in which astringents were dissolved, such as gallants, oak bark, etc. They did it, moreover, with a view of arresting bleeding. In more recent times the alcohol dressing has been made popular by Nelaton, who used it largely and found it of value.

Dionis also used alcohol with good results. M. Chédervergue asserts that "camphorated alcohol is, beyond contradiction, the best disinfectant that can be found for the treatment of wounds and ulcers," and others allege that alcohol dressing has without doubt a cleansing and disinfecting influence on a wounded surface, while, at the same time, it helps materially to arrest capillary bleeding and that serous oozing which is so detrimental to primary union.

I should not dare as yet to give any decided opinion, but I can say that I have used the alcohol treatment in very severe cases with fine results, and I will go further and say that I do not consider the use of carbolic-acid or corrosive-sublimate solutions essential in the treatment of wounds, stating with this opinion that I have operated for cataract in about thirty cases in which I used no antiseptic solutions, but simply hot water for my instruments and for the washing of the eye, and always had excellent results.

In a very severe case of ovariotomy, where there were numerous adhesions, I washed the abdominal cavity with hot water that had previously been well boiled was used for the toilet of the abdominal cavity, and no better results could be desired than were obtained in these cases.

The great ophthalmologist, Professor von Stellwag, of Vienna, never used, during the four months that I visited his clinics, anything more than boiling water for the disinfection of instruments, etc.

To conclude, I do not doubt for a moment the great antiseptic properties of carbolic acid or of corrosive sublimate, but I do believe that they are not essential in surgery, for equally good results are obtained with the use of simple hot water during the operation, and of alcohol in the dressing of the wound, as when the usual antiseptic solutions are used.

In the present case, after the resection of the femur, there was very little suppuration, there was no inflammation, and the highest temperature was, on the third day, only 101° F.; after that the temperature ranged between normal and 99-5° F. In this case hot water was used during the operation, and alcohol for the dressing.

The result of the operation is represented in Fig. 2. The shortening amounts to two inches and a half.

TESTS OF THE HEMOGLOBIN OF PREGNANT WOMEN.

By Ethel Blackwell, M.D.

In medical literature and medical practice such questions are often asked as, Are pregnant women anaemic? Is their haemoglobin drained away by the developing child? And many statements have been made regarding the matter. Hitherto comparatively little practical work has been done in this line, but now many investigators are busy with examinations in various directions on blood, and before long we may hope for more light on the subject.

For the past four months, while at the Woman's Medical College of the New York Infirmary, I have made some tests of the haemoglobin of pregnant women. The women were all normal cases—that is, none of them had any disease characterized by anaemia. I used the Reichert-Fleisch heamometer (hemoglobinometer). The locality tested was the ball of the middle finger of the left hand. The time at which the tests were made was as near 7 A.M. as possible, thus securing the same conditions for each test—namely, the relation to the third meal and exercise of the day—for more accurate comparison.

With the kind help of medical friends, it was possible to carry out work at the New York Infirmary for Women and Children, at the Emergency Hospital on Twenty-sixth Street, at the New York Infant Asylum, and at the Maternity Hospital on Blackwell's Island.

Tests were made on one hundred and sixty-three women:

<table>
<thead>
<tr>
<th>Date</th>
<th>Number</th>

</thead>
<tbody>
<tr>
<td>94</td>
<td>1</td>
<td>in the 9th month of pregnancy</td>
</tr>
<tr>
<td>38</td>
<td>8th</td>
<td>1</td>
</tr>
<tr>
<td>15</td>
<td>7th</td>
<td>1</td>
</tr>
<tr>
<td>13</td>
<td>5th and 6th months</td>
<td></td>
</tr>
</tbody>
</table>
The average reading on the Fleischl scale was in the
9th month = 51-3
8th " = 55-9
7th " = 49-8
1st " = 60-0
5th and 6th months = 51·5

Or the general average for all the months together was
54·2. Putting it in another way—
0·6 per cent. = 90·100
2·5 " = 80·90
9·2 " = 70·80
15·9 " = 60·70

It will be noted that the majority were between forty and fifty, and the next greater number were between fifty and sixty.

But having found that the general average was 54·2, or more accurately that 30·1 per cent. were between fifty and sixty, and 36·2 per cent. between forty and fifty, is it to be concluded that this is an anemic condition?

Compared with forty women students whom I tested at Bryn Mawr College in 1892, half of whom were between eighty and ninety, and the rest about equally divided between seventy and eighty and between ninety and one hundred, this was a distinctly anemic condition. But these pregnant women, it must be remembered, were of the servant class and subject to the air and conditions of New York city; and was this an anemic condition when compared with non-pregnant women of their own class?

I have been able to make one hundred tests on non-pregnant women of this class with which to compare, the greater number being made at an intelligence office.

A general average of 53·1 was found; or
4 per cent. = 70-80
12 " = 60-70
52 " = 50-60

We find for the pregnant women a general average of 54·2 compared with a general average of 53·1 of the non-pregnant women. Or to compare more accurately, we find 30·1 per cent. of pregnant women between fifty and sixty compared with 52 per cent. of non-pregnant women between fifty and sixty; 36·2 per cent. of pregnant women between forty and fifty compared with 28 per cent. of non-pregnant women between forty and fifty; and 15 per cent. of pregnant women between sixty and seventy compared with 12 per cent. of non-pregnant women between sixty and seventy. We see, then, that in general there is a condition of anemia in pregnant women, though this condition is by no means a striking one.

This result is obtained by comparing one hundred and sixty-three pregnant women with one hundred non-pregnant. If we take the first one hundred cases of the pregnant women (ninety-four obtained in the ninth month and six in the eighth month) and compare with one hundred non-pregnant women, we obtain from the one hundred pregnant women a general average of 54·5, or
3 per cent. = 80-90
10 " = 70-80
18 " = 60-70

Here again we reach the same conclusion.

The non-pregnant women were mainly between forty and seventy on the scale, while the pregnant women showed greater variation.

The further points in this article, though founded on a number of tests, are not based on so large a proportion of tests as are the previous statements, and therefore, though indicating a decided tendency, can not be taken as positive proof.

Twenty-three patients were tested in the eighth and ninth months of pregnancy, and again after delivery (within twelve days). The general average of these pre-partum was 50·5 and post-partum was 53·2; or, putting it another way:

<table>
<thead>
<tr>
<th>Pre-partum.</th>

</tr>
</tbody>
</table>

Showing a general decrease after delivery.

Besides these twenty-three post-partum tests, thirty-two more were made on patients who had not been tested before delivery, equaling a total number of fifty-five post-partum tests. Taking these fifty-five tests, and averaging those taken under six days after delivery (twenty-eight in number) with those taken from six to twelve days after delivery (twenty-seven in number), we find a general average in this first set of 53·2, compared with a general average in the second set of 56·8; or, putting it another way:

</tbody>
</table>

This shows a higher general average or a higher percentage in the later days after delivery. The probable explanation of this is the exhaustion and loss of blood during the first few days after labor.

It may be noticed in passing that the average of hemoglobin from the sixth to the twelfth days after labor—that is, after a week's rest—is higher than the average of the hemoglobin of non-pregnant women. But it must be
remembered that this is not proved, for we have only twenty-seven cases to compare with the one hundred cases of non-pregnant women.

At the time of taking twenty-one post-partum tests I also tested the patients' babies by the same method and from the same finger. This table is so striking that I insert it bodily.

It is evident that a large manufacture of red blood-cells has been going on in order to keep up this supply to the mother and this large supply to the child. Four of these cases were tested within twelve to sixteen hours after delivery, and it would be interesting to know how much of the manufacture was done by the mother and how much in the organism of the child itself.

</table>

Nos. 17, 18, 19, 20, and 21 are interesting for other reasons. Eighty and seven tenths and eighty-one were twin boys four weeks old; the mother tested at the same time was 44:7. Sixty and eighty-four were twin boys three days old, delivered through four incisions made in the cervix of an eclamptic mother. Sixty was the largest child, was born first, and his cord was tied immediately. Eighty-four was the smallest twin. The mother was thirty-nine at the same time.

Forty-five was the test of a baby (taken when three weeks old) who was born suddenly of a blind mother without help, and whose cord was in some way torn, allowing hemorrhage. The mother's test at the same time was 31:5.

The upper of these curves shows the readings of the babies plotted in the order of the tests taken.

The lower curve shows the mothers' readings. Each mother is plotted directly under her baby.

It is worth noting in passing that six of the first sixteen babies were a hundred or over. In adults very few tests of over a hundred have been recorded.

The question as to how much the blood of pregnant women was subject to variations during the day seemed to be worth considering. But these women were variable in appetite, and, of course, had little or no out-of-door exercise, and the variations their blood showed were irregular in time and amount.

Variations between 6.30 A.M. and 9 P.M., tests being made four or five times during the day, were:

<table>

<td>3.3</td>
</tr>
</tbody>
</table>

It will be seen that the variations were from 0.3 all the way up to 17. Or,

30 per cent. varied from 10 to 17.
47 " " " 5 to 10.
23 " " " 0 to 5.

Hence we see the need of like conditions, of time, meals, exercise, etc., as far as possible, in making hemoglobin tests, and we understand that their value is comparative and not absolute.

It would be interesting and of value to compare with this work tests of pregnant women whose conditions in life were those of comparative luxury and ease.

I want to thank most cordially Dr. Eleanor B. Killam, Dr. Auguste Parry, Dr. Henry McM. Painter, Dr. James Clifton Edgar, and others, for their very kind help in obtaining for me the opportunity for doing this work.
OBSERVATIONS ON EXCESSIVE INTESTINAL PUTREFACTION.*

By C. A. HERTER, M. D.,
Visiting Physician to the City (Charity) Hospital; 
Professor of the Anatomy and Pathology of the nervous system, 
New York University, 
and E. E. SMITH, Ph. D.

Attention was called, not long since, to the frequent occurrence of excessive intestinal putrefaction in epilepties; and observations were brought forward to show that in some cases of epilepsy the occurrence of this condition appears at times to determine the epileptic seizure.

The facts brought to light in the study of this subject stimulated an inquiry into the occurrence and character of putrefactive processes in the intestine in clinical states other than epilepsy. This inquiry, which has been carried on during the past three years, makes it clear that deviations from the normal character and degree of putrefaction in the contents of the intestine are met in association with a variety of morbid states. The preparation of the present paper was prompted by the belief that disturbances of this nature have received less attention than from their practical importance (in both diagnosis and treatment) they seem to deserve. The following has been written with the object of presenting, first, the evidence we possess as to the existence of putrefactive processes in the intestine; second, certain facts as to the clinical conditions in which putrefaction occurs in excess; and, third, the principles that should enter into the management of cases where such excess is present.

During many years the belief has been gaining ground that various conditions of disease may arise, in man, through the absorption from the gastro-intestinal tract of toxic substances formed within it. For example, clinical evidence has suggested that some kinds of headache, most cases of urticaria, the prostration and fever associated with certain attacks of diarrhoea, and even many cases of simple anaemia, may depend upon the entrance of toxic materials into the circulation.

The well-known immediate symptoms of constipation bear out this idea, and perhaps no more striking clinical evidence can be found than the non-septic post-partum rise in temperature familiar to every obstetrician, which rapidly subsides after a thorough emptying of the bowel. And yet, while a good deal might be said in favor of the toxemic origin of these and other states, it must be owned that the arguments for this view rest chiefly upon clinical considerations, and are at present unsupported by accurate knowledge of the nature of the pathological conditions involved.

A partial exception to this statement may be made in the case of processes concerned in the putrefaction of protid substances in the intestine.

It has long been known that a variety of aromatic sub-

* At present little is known of the special bacteria that give rise to the various products of putrefaction that are met in health and disease. The following facts relating to this subject have been ascertained:

Numerous micro-organisms are capable of inducing putrefaction of albuminous substances. In the initial stages of the process aerobic and facultative anaerobic bacteria usually play the most important part, while in active putrefaction they are supplemented or perhaps replaced very largely in the latter stages by strict anaerobes, organisms which have received comparatively little study. Among the facultative anaerobic bacteria probably the most important and ordinary excretors of putrefaction are the bacilli of the proteus group; they are of common occurrence and possess to a high degree the power to produce putrefactive decomposition. Proteus vulgaris (Hauer, Uher Fäulnisbakterien, Leipzig, 1885) and Proteus mirabilis, the commonest species, are liquefying motile bacilli and grow rapidly in the usual culture media at ordinary temperature. Other putrefactive bacteria are Bacillus colitis (Schatten, Der Rothlauf der Schweine, Wiesbaden, 1885), found in the intestine of a diseased pig; Micrococcus faecalis (Klauann, Allg. med. Centralzeitung, 1887, p. 1344), from the posterior nares of a man; Bacillus pyogenes faetidus (Passat, Untersuehungen über die eigene Phegmeose des Menschen, Berlin, 1885), obtained from an abscess of the anus; Bacillus putrefaciens coli (Bienstock, Uher die Bakterien der Fäces, Zeit. f. klin. Med., 1884, Bd. viii, from adult feces; Bacillus flavus liquefaciens (Fligge, Die Mikro-organismen), a very common form occurring in putrid infusions; Bacillus coli communis (Emmerich, Deutsche med. Wochenschr., 1884, No. 50), found in the air, in putrefying infusions, in normal and abnormal feces, and elsewhere; and Bacillus pyocyanus (Geisar, De la pyocyane et de son microbe, Thèse de Paris, 1882), occurring in green and blue pus, and probably a widely distributed saprophyte. Bacillus cohumi grandidi (Sternberg, Report on the Epidemiology and Prevention of Yellow Fever, Washington, 1891, p. 21) is a large bacillus obtained from the interior of dead animal matter in a state of putrefaction and belongs to the strict anaerobes.

When intestinal contents and normal feces are examined, a very large number of micro-organisms are to be found. Even the milk feces of sucklings are no exception in this regard, since normally at least two varieties of bacilli are present (Eckerher, Die Darumbakterien der Nànglings, 1886); Bacillus lactis acrogenes, which is more abundant in the small intestine and produces an acetic-acid fermentation of milk sugar, and Bacillus coli communis, most abundant in the large intestine, which, besides giving rise to an acetic-acid fermentation, occasions the formation of large quantities of lactic and formic acids. No true putrefaction occurs, however, since milk casein is not changed by these bacilli. In cattarial enteritis the alvine discharges contain a much larger number of micro-organisms, while in diarrhea associated with toxic symptoms one or more species of the proteus group appear to be constantly present (Boeker, Trans. of the Amer. Pediatric Soc., vol. i, 1885, p. 198). Thus the bacterial condition of milk faces is comparatively simple and well illustrates the relation that exists between bacterial growth in the alimentary tract and some forms of disease. But the intestinal contents of adults with a mixed diet present a far more difficult problem. Here a much larger variety and number of micro-organisms are normally present, producing changes in all the different classes of foods, including even putrid decomposition of proteins. Indeed, over fifty known species have been isolated from intestinal contents; and in addition to these are many unidentified and perhaps unknown species found in normal and pathological conditions. The commonest form appears to be Bacillus coli communis; probably certain strict anaerobes not yet carefully studied play an important part.

The particular products formed by albuminous putrefaction will de-
light by Banmann—namely, that these various aromatic bodies, however formed within the intestine, are at last eliminated from the body (if absorbed) through the urine, almost exclusively in combination with sulphuric acid, in the form of ethereal sulphates.

There is reason to think that other acids than sulphuric acid may enter into combination with the aromatic bodies formed in the intestine, but notwithstanding this the ethereal sulphates are undoubtedly the form in which by far the greater part of these bodies is eliminated. The ethereal sulphates therefore become an index of the amount of putrefactive products absorbed from the intestine, and the determination of their amount in the urine is an indication whether the putrefactive processes are or are not excessive.

This fact is the basis of the present study of intestinal putrefaction as well as of many previous investigations upon the same subject. It therefore becomes of the highest importance to inquire more carefully into the nature of the evidence on which this fundamental proposition rests.

Evidence that the Ethereal Sulphates of the Urine are derived from the Putrefaction of Proteid Substances in the Intestine.—We may now pass to the consideration of the evidence which proves that the ethereal sulphates of the urine are derived from the putrefaction of proteid substances within the intestine.

Sulphuric acid occurs in the urine in two combinations—first, as neutral salts of the alkalies, the so-called "preformed" sulphates; and, second, as ethereal or aromatic sulphates, which are combinations of sulphuric acid or acid sulphate of potassium with various aromatic substances, particularly indol, phenol, and skatol, and to a less extent with cresol and catechol or pyrocatechin. The quantity of sulphuric acid in this combination which is excreted daily by normal adult individuals varies considerably both in the same and in different persons. We have found that in most persons the daily output ranges between 0.12 gramme and 0.25 gramme.* The quantity excreted by the urine of course gives us no information as to the proportion in which the sulphuric acid is combined with indol, phenol, skatol, etc., since these individual and special combinations constitute no fixed proportion of the total. In most cases in health the combination with phenol, phenol-potassium sulphate, is the most abundant of the ethereal sulphates.

It is known that the aromatic substances are occasionally eliminated through the urine in combination with glycuronic acid, but this occurs in the urine in such small quantities that, except after the administration of certain drugs, it may be considered to be practically absent.

The various ethereal sulphates of the urine were at one time thought to be derived from the aromatic substances taken with the food, in much the same way that hippuric acid and its salts may originate. Some kinds of food taken by man may furnish the material for the formation of ethereal sulphates in small amount, and under these circumstances this may explain the presence of a small part of the aromatic sulphates; but, as a rule, the food of man contains little of an aromatic nature, and it has been found that upon an ordinary diet the ethereal sulphates from this source amount to practically nothing.

This view of the origin of the ethereal sulphates had therefore to be abandoned. It was replaced by the theory of Salkowski,† who, as late as 1886, expressed the belief that one of the ways in which the ethereal sulphates arise is through their formation in the tissues of the body. The facts which seemed to give support to this view were as follows: Salkowski‡ found that in starving animals the urine contained large quantities of indoxyl-potassium sulphate (indicam). Another observer, R. Van der Velden,§ found that the ethereal sulphates were reduced only one half in a dog which had been kept without food for periods of five and six days. Further, Senator,‖ studying cases of chronic inanition in human beings, observed that in many instances the urine contained an abnormally large amount of a particular ethereal sulphate—indoxyl-potassium sulphate (indicam). It is, of course, easy to see how these facts might be interpreted to support the theory of the formation of the aromatic sulphates outside the alimentary tract—that is, in the tissues themselves—but the classical observations of Banmann ‡ were destined soon to put an entirely new aspect upon the matter. These observations were made upon a patient who for many weeks passed the intestinal contents through a fistula in the upper portion of the small intestine. Banmann found that during the

* These figures are based on a large number of personal observations. Von Noorden gives the same figures; but, as he points out, the amounts may exceed or fall below them without necessarily being pathological.

‡ Berichte der deutsch. chem. Gesellschaft, Bd. ix, S. 408.

§ Ueber die Ausscheidung der geparten Schwefelsäuren im Harn. Virchow's Archiv, Bd. lx, S. 343, 1872.

entire period in which the intestinal contents were diverted through the fistula there was a remarkable diminution in the amount of the ethereal sulphates in the urine, indol, phenol, and the aromatic oxycids being present in mere traces. Just as soon as the fistula was closed a pronounced increase occurred in the amount of the ethereal sulphates excreted by the urine. The interpretation very properly given these results was that the occurrence of putrefaction in the contents of the intestine is the cause of the production of the ethereal sulphates, these substances appearing in the urine when the faeces are passed by the anus because of the opportunity then given the intestinal mucous membrane to absorb whatever putrefactive products are formed in the gut, but disappearing very largely when the intestine is emptied above by the artificial anus, because putrefaction of the intestinal contents is only just beginning at this stage of digestion, and the amount of the putrefactive products capable of being absorbed by the mucous membrane is very small. In the light thrown by these crucial observations of Baumann, some earlier studies made by Ewald became significant. Ewald had in 1878 made observations upon a case of intestinal fistula resembling Baumann's, and had noticed that, so long as the chyme was discharged through the opening, the urine was free or nearly free from phenol and indol, but that these substances reappeared in normal or excessive amounts as soon as the faeces were passed per anum. A very satisfactory and interesting confirmation of the results of Baumann and Ewald, from another point of view, was furnished in 1888 by Kast and Baas. Their observations were made upon a case of complete occlusion of the small intestine from cancer. The occlusion persisted twenty-three days, and during this time a large amount of the ethereal sulphates was regularly found in the urine. At the end of this period the stoppage was relieved by operation, and there at once followed a great diminution in the amount of aromatic sulphates excreted. We have ourselves observed a very large increase in the ethereal sulphates and in indol in a case of occlusion of the small intestine in the jejum from external pressure at the time when this stoppage was established. Pointing in the same direction are the results obtained by Baumann and Wassilieff, who found that there was a complete disappearance or at least a great reduction in the ethereal sulphates eliminated by starving animals when the contents of the intestine were pretty well got rid of by the use of large doses of calomel for several days. More, working a few years later, got practically the same results with calomel. He found also that very large doses of iodine in dogs freed the urine temporarily from the presence of ethereal sulphates. All these results, reached as they have been by competent observers, furnish strong evidence that the tissues in health have nothing to do with the formation of aromatic sulphates, and the conclusion is justified that intestinal putrefaction is in health the sole source of their formation, barring only the trivial influence of food containing aromatic substances.

In connection with the view that the ethereal sulphates might be formed by the tissues it is of interest to note that Müller was unable to find any evidences of the presence of these aromatic putrefactive products in the muscles and parenchymatos organs in health. He found, however, that the faeces of starving animals contained indol, and this fact was only an additional confirmation of the correctness of the view that the presence of ethereal sulphates in the urine of starving animals does not constitute any evidence that their production occurs in the tissues, but is far better explained on the ground already mentioned. It should further be borne in mind that, as already mentioned, Kühne and Neeki have shown conclusively that indol is exclusively the product of the action of bacteria upon proteins. If it should be held that possibly the aromatic substances may be produced by the action of bacteria in normal tissues, the fact should be remembered that Meissner, Zahn, and Hauser were unable to find bacteria in normal tissues. The Bacillus coli communis has indeed been repeatedly found in spleens that were apparently normal, but only, we believe, where there has been ulceration of the intestinal mucous membrane.

The view that the ethereal sulphates arise as the result of intestinal putrefaction is the only view which accords with observed facts. It does explain these facts fully, and is supported by a large amount of satisfactory experimental and clinical evidence. It may be added that, so far as we are aware, this explanation of the origin of the ethereal sulphates of the urine has been accepted by all modern writers upon chemical physiology and pathology.

We must note one important exception to the origin of the aromatic substances from the putrefaction of proteins in the intestine. The ethereal sulphates may be increased in consequence of putrefaction in other parts, especially where there is extensive suppuration without free drainage. Such an increase has been observed in abscess in various parts, in tuberculous lung cavities, and in cases of empyema. It is scarcely necessary to emphasize the importance and the difficulty of excluding intestinal sources of excess before concluding that an excess of the combined sulphates, or of any particular product of putrefaction, is due to a suppurrative process.

The use of certain drugs of an aromatic nature may enormously increase the output of the ethereal sulphates, and may lead to serious error if the origin of the excess be not appreciated. Thus we have found a great increase from the use of salol in two individuals, the increase being

‡ Zeitschr. f. physiolog. Chemie, Bd. vi, S. 112.

* Indicanausscheidung durch den Harn bei Insuffizienz. Mütthel, d. Würzburger mediz. Klin., Bd. xi, S. 342–358, 1888. Ortweller (ibid., S. 153) found that in fever, with increased destruction of tissue, there was no increase of indican; but this fact cannot properly be used as an argument against the formation of ethereal sulphates in the tissues.
† Berichte d. deutschen chem. Ges., Bd. xvii, 1875, S. 296.
Herter and Smith: Excessive Intestinal Putrefaction. [N. Y. Med. Jour.]

The use of croesote must be attended with the same result. Von Jakisch has recently called attention to a largely increased output of aromatic sulphates noted by him in a patient who had been poisoned with benzol, the increase being doubtless due to the combining of the drug with sulphuric acid.

How are we to decide whether, in a given case, the ethereal sulphates are in excess or not, whether we have or have not to deal with an example of excessive intestinal putrefaction? This is a question of the highest practical importance, for unless our criterion of excess be essentially accurate there is danger of falling into grave error in the interpretation of results. As already stated, the quantity of sulphuric acid excreted daily in health as ethereal sulphates varies ordinarily between such wide limits as 0.12 grammes and 0.25 grammes.† But the quantity may be increased to 0.3 grammes or even 0.4 grammes without our being able to say from the quantity alone whether we are dealing with an excess, for the quantity of protein food ingested may be very large, and we should expect that the opportunity for the activity of putrefactive bacteria would be greater in this case. On the other hand, the amount eliminated may lie between the figures mentioned, and thus be apparently normal. But the quantity of protein food may have been unusually small, so small and of such a kind (milk, meat) as to be accompanied in perfectly normal digestion by the elimination of even less than 0.12 grammes in the day. The mere amount, therefore, does not afford a thoroughly satisfactory criterion, though it is a help, and should always be regarded. A consideration of the ratio of the ethereal to the total or preformed sulphates is an important aid to the interpretation of the results.

The value of taking into account this ratio was first emphasized by Van der Velden, and its utility has been appreciated by many subsequent writers. The use of the ratio is based upon the fact that in normal persons the average ratio of the ethereal to the preformed sulphates is not higher than 1 to 10 or perhaps 1 to 9, and is often as low, even on a mixed diet, as 1 to 12 or 1 to 15. Indeed, in our own experience, persons in the best of health have more frequently a ratio in the neighborhood of 1 to 12 than 1 to 10. The sulphates have nothing whatever to do with putrefaction in the intestine, but are derived in the metabolism of protein food from the sulphur which this contains, and it thus happens that the total sulphates bear a relation to the amount of protein absorbed, which in turn is related to the amount of protein food ingested. When, therefore, we say that the ratio of the combined to the preformed sulphates is found to be in the neighborhood of 1 to 10, without much reference to the amount of protein food ingested, this is very much the same as saying that in normal conditions the opportunity for the activity of putrefactive bacteria in the intestine seems to be proportioned to the amount of protein food taken. The use of the ratio is thus equivalent to taking into consideration the amount of protein food ingested and absorbed. The total sulphates, as might be expected, are found to bear a fairly constant relation to the amount of urea—the actual ratio being from 1 to 10 to 1 to 14, in most cases not far from 1 to 12. This ratio, as we have found, is often singularly constant in a given individual. We might, therefore, make our comparison between the ethereal sulphates and the urea; but this is less convenient in practice than to make the comparison with the preformed sulphates. If, however, the sulphates become disproportionate to the urea, as they occasionally do, we can not rely upon the ratio, but should take into consideration what the ratio would have been if the sulphates had been normal. This rather roundabout course is not thoroughly satisfactory.

It should be mentioned that some writers (F. Muller, Kast and Baas, Salkowski, and von Noorden) object to the use of the ratio on the ground that if we compare the ethereal sulphates which arise exclusively from intestinal putrefaction with the total or preformed sulphates which are derived from the metabolism of proteins and have nothing to do with intestinal putrefaction, we are comparing incommensurable things. While it is perfectly true that the two kinds of sulphates have a different meaning, the considerations above referred to render this comparison reasonable and practically useful, and this view is shared by many actual workers upon the subject, including Biernacki, Rovighi, G. Hoppe-Seyler, and E. Baumann. But though we advocate strongly the use of this ratio as a criterion of the output of the ethereal sulphates, we recognize fully the fact that it should not be employed blindly, and that even when employed with every precaution there are occasional cases in which it is difficult to reach a satisfactory conclusion as to whether the ethereal sulphates are present in excess or not.

In the preceding we have considered some of the fundamental facts relating to the aromatic sulphates as a group. We may now review to advantage certain facts relating to particular members of this group, especially indoxyl-potassium sulphate and phenol-potassium sulphate.

† Loc. cit., S. 55.

† In one case where the subject had been excreting about 0.290 grammes of ethereal sulphates daily on a mixed diet, the amount rose to 0.416 grammes and 0.602 grammes on ten grammes of salol three times a day, and to 0.953 grammes, 0.955 grammes, and 0.966 grammes on twenty grammes of salol daily. The ratios were 3.2 and 1.7, and 0.9, 0.9, and 0.9 during the two periods respectively.
‡ In Fall von anschweizender Vergiftung mit Benzol. Ber. klin. Wochenchr., February 27, 1892.
§ Calculated as H₂SO₄.
Indoxyl-potassium sulphate, or indican, is practically the most important of the ethereal sulphates, partly because of its relation to pathological conditions and partly because of the readiness with which its presence is ascertained, which has led to much more general observations upon it.

It is derived from an aromatic volatile substance, indol, which is formed in the intestine from putrefaction of proteids. Indol has the formula C_9H_7N. By oxidation indoxyl, C_9H_8NO, is formed, which is eliminated in the urine as indoxyl sulphate of potassium, C_9H_8NO(SO_4)\_2. The latter substance, when pure, crystallizes in white glancing tablets and plates. It was called indican in the mistaken belief that it is identical with the indican of plants, and the name has clung to it on account of its convenience. When this indican undergoes oxidation indigo blue is formed, and gives to the urine a characteristic blue color. Indigo blue is not indican; its presence is evidence of the pre-existence of indican in the urine. The reaction by which the change into indigo blue occurs is as follows:

\[ 2C_9H_8NO(SO_4)_2 + O_2 = C_9H_8NO_2 + 2H_2SO_4 \]

Indoxyl-sulph. of potassium, Indigo blue. Pot. hydrogen sulph.

If it is difficult to determine what constitutes an excess of the ethereal sulphates in some cases, it is even more difficult to say exactly how much indigo blue a urine may yield and still be normal. We believe that it is safe to make the general statement that the quantity consistent with a high grade of health and well-being is very small.

The occasional appearance of small amounts of indican in the urine of an adult does not necessarily mean any appreciable disturbance of digestion, but the regular occurrence of even moderate amounts is always associated, in our experience, with evident digestive disorder, and must therefore be regarded as abnormal. It is hardly possible to express by figures the smallest quantity of indigo blue in the twenty-four-hours' urine which must be regarded as pathological, for it is necessary in every case to take into consideration whether the patient is robust or feeble, and whether the condition of health is less good when indigo blue is present than when it is not—whether or not symptoms can with reason be associated with its presence. But it is probably correct to say that the quantity of indigo blue in the urine which amounts to a mere trace (corresponding to say one to two milligrams in the twenty-four hours) can not be considered distinctly pathological, while an amount greater than five milligrams in the twenty-four hours (an amount which gives a weak but distinct reaction with the Jaffé test) must in the great majority of persons be so considered. An even smaller amount of indigo blue in the urine of children under say five years of age is to be considered pathological. In our experience we have never met with indican in amounts greater than traces without this being associated with evident disorder of digestion. It may indeed be questioned whether in children even a trace can be considered strictly normal. These statements are based upon the examination of a large number of urines from carefully studied cases.

According to Senator*, the urine of newly born chil-

dren contains no indican. We have made only a few observations on children at this time, but have never found even traces.

Since indican is an ethereal sulphate, the question naturally occurs to one, Is the relation of this substance to the total ethereal sulphates of the urine a fixed or a variable one? It may be said that there is in general a rough correspondence between them, that when indican is present in large amounts the total ethereal sulphates are apt to be excessive, and when indican is absent we are rather more apt than not to find the total sulphates normal. But to these rules there are so many exceptions that one almost hesitates to speak of them as rules. There are many cases where the ethereal sulphates are normal both as regards totals and ratio, where indican is present in pathological amounts and perhaps in greatly increased amounts. There are likewise cases, and they are even more numerous than those just mentioned, where the total ethereal sulphates are in pronounced excess, but where indican is altogether absent.

Pathological quantities of indican have been found in a great variety of different conditions. Salkowski* has observed such an increase in perityphlitis and peritonitis; Brieger,† in chronic anemias and cachexias; Jaifc,‡ in malignant disease of the intestine; Senator,§ in chronic peritonitis and cancer of the stomach; De Vries,¶ in tubercular peritonitis and obstruction of the small and of the large intestine; Hennings,¶ in pernicious anemia, typhus, cholera, leucoc, phthisis, acute and chronic gastritis, chronic suppuration in any part, progressive muscular atrophy, and Addison's disease; Gutmann,‖ the exudate of pleurisy—and this list might be much extended. In every case where indigo blue is obtained in pathological amounts the condition may be referred to the putrefaction of proteid material, usually within the intestine, but sometimes outside it in the tissues. Just what are the special conditions that give rise to the increase of indican rather than the other aromatic sulphates we can not say. In all probability the aromatic bodies formed in putrefaction in the intestine vary, among other influences, with the kinds of bacteria which exist in the intestine. According to Lewandowski§ certain bacteria produce both indol and phenol, while others produce either indol alone or phenol alone. But the study of this aspect of the subject is only just begun.

Some observations have been made upon the influence of the digestive secretions in the formation of indol. Thus, according to G. Pisenti, indican depends largely upon the activity of the pancreatic juice. This view is based upon experiments on dogs, in which it was found that the

† Zeit. f. physiol. Chem., Bd. xii, S. 221.
‡ Arch. f. gesammte Physiologie, Bd. xxx, S. 455, and Crlbl., f. die med. Wissensch., Nos. 31-32, 1872.
¶ Indolbildende Substance in einem Exhume, Deutsch. med. Wochenschr., No. 51, 1887.
¶ Deutsche med. Wochenschr., 1890, No. 51, S. 1196. See also Baumann, Zeit. f. physiol. Chem., who states that indol is formed in large amount by the common bacillus of cholera.
amount of indican in the urine grows much less (after first increasing) when the pancreatic juice is experimentally cut off. Pisenti* further regards the disappearance of indican in high fever, when the pancreatic juice is no longer secreted, as bearing out his conclusion. But though these observations are not sufficiently numerous to be regarded as conclusive, even upon the question whether the shutting off of the pancreatic juice regularly influences the formation of indol, it seems to be highly probable that the action of the pancreatic juice in producing tyrosine is an important, though not necessary, condition for the production of indican. We know, further, from the very interesting studies of Ernst, that so long as the bile is present in the intestine it is possible to have indol formed in large amount, probably because of the fact that the mucus of the bile furnishes material very favorable for certain kinds of putrefactive decomposition. This latter observation is of especial interest in connection with the circumstance, to be emphasized later, that catarhal conditions of the small intestine are associated with the output of indican in pathological amounts.

According to de Vries † and Filati, ‡ the small intestine is exclusively concerned with the formation of indol, in distinction to the large intestine, in which, according to Filati, skatol is the chief aromatic body formed. But this generalization, though attractive, is not as yet based upon sufficient evidence to enable us to accept it without hesitation, though it is to be noticed that the researches of Ernst, mentioned above, accord in some measure with this view.

Opposed to it are the direct observations of Macfayen, M. Nenciki, and N. Sieber. They, in a case of intestinal fistula, withdrew the contents of the intestine through a fistula at the lower end of the ileum and found an entire absence of putrefactive products and an almost entire absence of putrefactive organisms, the decomposition present, referable to micro-organisms, being limited to carbohydrates. These observations do not, however, exclude the possibility of the putrefaction of proteids in the small intestine in catarhal or other abnormal conditions.

A substance which is formed in considerable amount in intestinal putrefaction is carbolic acid or phenol (C₆H₅OH). It may be derived in part in the intestine from the breaking up of tyrosin. It is absorbed as phenol, but somewhere in the body (the liver, according to Baumann) is converted into phenol sulphate of potassium.

(Yale University.—The annual address in medicine will be given in Battell Chapel on Tuesday, the 25th inst., at noon, by Dr. T. Mitchell Prudden, of New York, on the subject of New Outlooks in the Science and Art of Medicine. In the evening the medical faculty will hold a reception in honor of Dr. Prudden at Dr. William H. Carmalt’s house.

REPORT OF
SOME CASES OF FIBROUS ANKYLOSIS TREATED BY ELECTROLYSIS.*

By FRED WALKER GWYER, M.D.,
ASSISTANT PROFESSOR OF SURGERY, UNIVERSITY OF THE CITY OF NEW YORK; SURGEON TO BELLEVUE HOSPITAL; CONSULTING SURGEON TO BETH ISRAEL HOSPITAL.

In the spring of 1893 I prepared a paper on Electrolysis in the Treatment of Fibrous Ankylosis for reading before the New York Surgical Society, which was published in the Annals of Surgery, August, 1893.

The interest shown in this subject, as evidenced by numerous letters received, has encouraged me to select it for a further paper, which I have the honor to present to this society.

The method of application I gave in detail in the former paper, and it will suffice if I mention, before proceeding to the cases I wish to report, that I make use of the continuous current, moderately large electrodes, and a solution of ammonium chloride. The current is passed directly through the joint, with the negative pole nearest the adhesions. The application lasts from ten to thirty minutes, and is repeated every two to five days. The amount given depends on the susceptibility of the patient to pain, the condition and amount of reaction of the skin, and the size of the electrodes. It will range from forty to one hundred and fifty milliamperes.

Case I.—Mr. H., aged twenty-two. In August, 1892, he received a Pott’s fracture of the left ankle. On January 17, 1894, he was sent to me for galvanism by Dr. W. H. Thomson.

Examination.—The patient complained of pain after moderate use of the foot, stiffness especially marked in the morning, and after excessive use, such as an evening’s dancing, the foot would be stiff and sore for two or three days. Physical examination showed a slight deformity, and he was barely able to put the heel to the ground when standing erect with feet together. Motion at the ankle was not more than five degrees.

After one month’s treatment (twelve applications) he had about twenty degrees of motion, which was freer; also he had considerably less discomfort and pain after prolonged use.

The treatment was continued another month, but without further benefit.

Case II.—Miss W., aged twenty-five years, was sent to me by Dr. W. H. Thomson on April 17, 1894, with a history of acute articular rheumatism in the previous September, which left her with a partial ankylosis of the right elbow and left middle metacarpophalangeal joints.

Elbow: Pronation and supination perfect.
Flexion and extension before treatment..... 74°
After fifth application 83-5°
After twelfth application 98-5°

Gain 24-5° (33%).

Middle finger:
Flexion and extension 9°
After fifth application 25°
After twelfth application 36-5°

Gain 27-5° (305%).

* Read before the Society of Alumni of Bellevue Hospital, May 1, 1895.
The twelfth application was made on May 16th. Improvement continued during five or six subsequent applications and gradually stopped. Electricity was then discontinued.

Before treatment the patient was unable to perform numerous duties, such as dressing the hair, buttoning a dress, piano-playing, etc., except with great discomfort, all of which had disappeared when treatment was stopped.

Case III.—Mr. L., aged thirty-one years. On September 18, 1894, he fell and received a Colles’s fracture of the left wrist. Was treated in splints for nine weeks. Ten weeks after the accident he was sent to me, and I found on examination the wrist to be almost stiff; at most he had ten degrees of motion. Swelling was marked and he had pain on the slightest motion.

After two applications complete motion was restored, there was an absence of all pain, and the swelling was much reduced. He resumed work the following week.

Case IV.—Mrs. M., aged twenty-six years. Entered Bellevue Hospital in June, 1894, with a diagnosis of tubercular synovitis of the knee. She was treated until November 18th by plaster immobilization. She was then treated by galvanism.

Before treatment: Total motion = 5°
After second application = 15°
After ninth application = 29°

Gain = 24° (480%).
Duration of treatment, twenty-one days. Nine applications of one hundred and twenty milliamperes for fifteen minutes.

Case V.—Mr. N., aged twenty-five years. Received a fracture of the left patella on August 2, 1894. On removal of the dressings there was found entire absence of active and passive motion. During the interval from that time till November 18th, when electricity was begun, he gained some motion.

After third application, total motion = 15°
After tenth application = 42°

Gain = 27° (180%).
Duration of treatment, seventeen days. Seven applications of one hundred to one hundred and twenty milliamperes for fifteen minutes.

Case VI.—Mr. O., aged twenty-three years. Entered Bellevue Hospital with a supposed tubercular synovitis of the left knee. The joint was opened and the condition found to be non-tubercular. After closure of the wound motion was limited and accompanied by grating; the swelling was marked and the patient walked with a limp caused by pain.

On November 18, 1894, the galvanic current was applied.

After first application, total motion = 52°
After eighth application = 112°

Gain = 60° (115%).
The eight applications covered a period of forty-three days, after which the patient left the hospital with the above indicated gain in motion, much less swelling, no grating, and he walked without pain or limping. One hundred to one hundred and twenty milliamperes were applied for fifteen minutes.

Case VII.—Master P., aged eight years. Entered Bellevue Hospital with a traumatic synovitis of the left knee. Plaster immobilization was applied for four weeks. Galvanism was begun immediately on removal of the plaster (November 18, 1894).

After first application, total motion = 3-5°
After second application = 20-5°
After fifth application = 90°

Gain = 86° (2150%).
Duration of treatment, fourteen days. Five applications. When discharged, there was but little swelling, and the patient could walk very well and without pain.

Case VIII.—Miss Q., aged nineteen years. In August, 1893, this patient had an attack of rheumatic arthritis which resulted in stiffness of the right knee in the straight position.

On November 30, 1894, when I first saw her, there was practically complete ankylosis, there being but the slightest perceptible motion between the femur, tibia, and patella.

The galvanic treatment was begun and continued faithfully with three applications a week until April 6, 1895. During this time about ten degrees of motion was produced and the patella became slightly movable.

On April 6th, under ether, the adhesions were broken forcibly until flexion to a right angle was obtained, the patella also being freed. Two days after, there having been but slight reaction following the traumatism, electricity was again begun and has been continued to the present time with no improvement. The patient is extremely sensitive and intolerant of pain, and has aided me little or none during treatment.

Case IX.—Mr. R., aged fifty-three years. On October 14, 1894, this patient fractured his humerus in the lower part. On removal of the dressings, the elbow being found somewhat stiff, the galvanic current was applied.

Before application, total motion = 72°
After fourth application = 102°

Gain = 30° (41-3%).
Duration of treatment, twenty-four days.

Case X.—Mr. S., aged sixty-four years. On September 27, 1894, the patient received a fracture of the surgical neck of the left humerus. When the dressings were removed there was found but limited motion at the shoulder and elbow.

December 6, 1894, began applications of the galvanic current to the shoulder and elbow.

Elbow: Before application, total motion = 24°
After fifth application = 77°

Gain = 53° (213%).
Duration of treatment, twelve days. Five applications. The notes received give no specific record of the improvement at the shoulder, merely stating that “motion at the shoulder was greatly increased from the first application.” I report the case as an illustration of the benefit derived in cases of loss of motion following disuse.

Case XI.—Mr. T., aged twenty-one years. About 1890 the patient injured his right elbow. In 1893 Dr. George Woolsey operated and found bony union between the humerus, radius, and ulna, which he relieved.

On January 9, 1895, he appeared for further treatment.

Before application, total flexion and extension = 70°
After first application = 76°

Gain = 6°

The patient did not return, and has not been seen since.

Case XII.—Mrs. U., aged thirty years. In January, 1895, the patient received a Colles’s fracture of the left wrist, which was treated by splints for five weeks. On removal of the dressings motion at the wrist was limited and painful. Edema appeared promptly, but was not marked.

Electricity was applied three times a week for two weeks, when there was almost complete motion and disappearance of the swelling, with good use of the hand and fingers.

Case XIII.—Mr. V., aged thirty-five years. In January, 1895, the patient sustained a dislocation of the left shoulder,
Was in dressings four weeks. There was then found atrophy of the shoulder muscles and very limited motion, which was painful.

Electricity was applied three times a week for three weeks; at the end of this period all motions of the shoulder were normal and without pain, and the muscles had regained in great part their size and tone.

I have treated a number of other cases of which the above-mentioned cases are types in a degree and give a fair idea of the classes of cases suitable to this treatment and the result that may be expected.

The majority of these cases were treated at Bellevue Hospital, where the regularity of application and length of time of each were necessarily interfered with; also the patients were often hard to control, insisting on their discharge as soon as enough motion was obtained to enable them to work, and before a cure was effected. This explanation will, I hope, answer the criticism as to why so few cures are reported.

A study of the results obtained will force the following conclusions:

1. That the best results are obtained in cases of injury.
2. That the shorter the interval between the injury and the beginning of the galvanic treatment, the more rapid and the greater the improvement.
3. That the greater improvement is exhibited after the first few applications, and then it is slow.
4. That all cases of injury showed great and immediate improvement. In disease it was much slower, and in two of the five cases failed.
5. That the improvement was marked in the following directions:
   1. Increased motion.
   2. Lessened pain.
   3. Reduced swelling.
   5. Increased general usefulness.
6. That it is applicable and very satisfactory in all cases of fibrous ankylosis, especially of recent origin, and to be recommended in cases of injury particularly, and that it should be applied immediately on removal of dressings as a routine treatment.

While the application is more or less painful, the improvement is so marked that no patient is unwilling to have it continued.

I wish to express my thanks to Dr. R. M. Taft, of the Bellevue staff, for help in collecting the cases.

Castration:
A Simple, Easy, and Rapid Method of Performing It.
By H. H. Kane, M. D.

Having performed the operation of castration a number of times, both for the radical cure of prostatic enlargement and for other purely local diseases of the testicles, I have of late been following a procedure that affords, I think, manifest advantages over the ordinary operation. This is especially true where the subject is over fifty years of age, and where prolonged etherization is apt to produce bad after-results. The rapidity with which this operation can be done, consistent, of course, with thoroughness and safety, is, it seems to me, a very important factor in its success.

Furthermore, as in the majority of cases where castration is necessary, or at least is performed, every measure that will reduce to a minimum shock or after-calls upon the system for the healing of a large surface, even if a primary union is obtained, will manifestly lessen the primary and secondary dangers of the operation, and yield better after-results.

Professor White states that he has frequently performed the operation for total removal of both testicles in three minutes. This may be possible in the hands of an expert surgeon as Professor White; but the majority of operators will find it exceedingly difficult, after the patient is etherized, to make the long incision on each side of the front of the scrotum, tie both cords by double ligature, peel out the testicles, and close each long incision by a number of interrupted sutures in three minutes' time. This is even more difficult where, as in the majority of cases, there is considerable hemorrhage from small vessels that have been divided or torn through, that must be twisted or ligated.

With a view of reducing the time necessary for keeping the patient under ether, decreasing the shock, and limiting the length of the incision, as well as producing perfect coaptation of the cut edges, avoiding the necessity
of drainage-tubes, insuring union by first intention, and doing away with the consequent drain upon the system where prompt union is not secured, I have recently performed the following operation, and can commend it as both simple and successful:

The pubes being shaved, thoroughly cleaned with soap and water, and rendered aseptic with a one-to-three-thousand bichloride solution, the scrotum is grasped in the left hand, and diagonal incisions of about an inch in length are made upon each side of the root of the penis, commencing just below the external ring. The cord on each side is seized and drawn out by means of a blunt tenaculum, is pierced with a sharp aneurism needle threaded with a heavy double catgut ligature, and is tied each way after the removal of the needle. The scrotum, which has been resting between hot sponges to thoroughly relax the tissues, is then drawn well down so as to include both testicles in the grasp, a Henry's scrotal clamp is applied, and both testicles are removed, together with that portion of the scrotum included in the clamp, to within about an inch of the posterior portion of the root of the penis.

![Fig. 1.—Showing the three original incisions.](image)

After removing the outer flange of the Henry clamp, the clamp is slightly relaxed, all bleeding points are secured, and the edges are then closed by interrupted sutures of catgut. The two short incisions just below the groin are closed in the same manner, after pulling out and cutting short the stumps of the two cords, and the catgut ligatures, cut off close to the knot, are allowed to drop into the wound. Before applying the Henry clamp and removing the scrotum it is well, as a matter of precaution, to pass a warm and well-oiled sound into the urethra, so that by no mishap the canal may be injured.

The wound is now dressed with a layer of protective tissue, after having been thoroughly cleansed and rendered aseptic, and upon this are placed from six to ten layers of iodoform gauze and above this six or eight layers of sub-

![Fig. 2.—Showing the three incisions closed by interrupted sutures and the scrotum shortened.](image)

limate gauze. Cutting a small piece of strong cardboard or sole leather into the shape of a horseshoe, and slipping it underneath the scrotum and its dressings, thus keeping them away from the anus, does away with the necessity of a bandage of any kind. Over the last layer of gauze I place a sheet of rubber tissue, perforated so as to admit of the passage of the penis, and thus not only keep the dressings clean in case of any dribbling of urine, but prevent the contamination of the wound in any way. Union by first intention is the rule. The whole operation is performed in a very few moments and the results are satisfactory in the extreme, the patient's temperature rarely rising above the normal.

I shall soon have the pleasure of reporting five cases of castration for enlarged prostate gland, with full details as to the measurement of the urethra, size of the prostate gland, etc., with the confirmatory evidence of other physicians who examined the patients before the operations and were present during the same.

The plan suggested by Professor Bryson, of Cleveland, of making deep injections of cocaine into the substance of the cord itself and of the scrotum, and thus making this operation absolutely painless and without the necessity of using ether at all, is a very interesting one, but one which I have tried but once.

June 7th.—Since writing the foregoing I have performed the operation of double castration with slight modifications of the method above described. Instead of using the Henry clamp across the scrotum and making a transverse incision, I placed the clamp from before backward, running from in front of the anus to the root of the penis.

After removing the scrotum and testicles, which was very rapidly done, and which was followed by very little bleeding, I closed the wound by interrupted sutures, and this will give, I think, a much better result than the transverse incision. It certainly leaves no pocket for the collection of purulent matter, and the wound practically heals itself.

Since the operation there has been no rise in temperature, and the patient, who had been urinating, by means of the catheter only, every hour for the past five years, was able within twenty-four hours after the operation to go in comfort an average of four hours, and rises from the bed to pass the catheter upon himself; his temperature has not
PREDISPOSITION OF CHILDREN TO LUNG COMPLICATIONS

AS A RESULT OF WHOOPING-COUGH, SCARLET FEVER, OR MEASLES.

BY FRANK McMORROW, M. D.,
SURGEON, SOLVAY PROCESS, ETC.

The predisposition of children to lung complications following infectious diseases is favored either by allowing the freer entrance of germs, or by a weakening of the powers of resistance.

In those rachitic children who have gone through a severe attack of pertussis, measles, or scarlet fever, their vitality, which was very weak from the first, is now almost exhausted, and changes easily take place in the respiratory tract, giving rise to bronchitis or broncho-pneumonia, which comes on insidiously.

If, after our case has commenced to improve, the temperature still remains high, the pulse more or less accelerated, and the general condition of the child remains poor, or becomes worse, we then suspect, before we auscultate or percuss the chest, that some changes in pulmonary structure have taken place. One of the most common sequels is a wide spreading of broncho-pneumonia. It runs a very tedious course, and causes considerable annoyance, especially to the young physician who has worked hard to bring his case through successfully, and at the end finds that he now has a complication to treat in one who is almost exhausted from paroxysms of coughing, and whose vitality is so much lessened as to be unable to withstand a siege of such severity. Most of these cases, on account of the lessened resistance of the child, result disastrously. In one whose general nutrition has been impaired, tuberculosis is very likely to develop, and many a case of consumption can be traced as following whooping-cough or measles.

Professor Edward G. Janeway said he was always suspicious of a child who, during convalescence from the above-named diseases, continued to cough, and whose temperature remained high. He watched the child carefully and made repeated examinations, and in the majority of cases his suspicions were confirmed.

The lung complications of whooping-cough are of inflammatory origin, bronchitis and pneumonia being the most frequent. In almost every case of pertussis we have in a mild form inflammation of the bronchial tubes; but when the inflammation extends to the minute tubes we have a more serious difficulty to deal with. Bronchitis is accompanied by increased respiration, accelerated pulse, and higher temperature. The amount of danger involved is in proportion to the dyspnea. Pneumonia is less common than bronchitis, but it is a very frequent complication, as the congestion which results from the cough predisposes to its development. The signs and symptoms that prevail in a case of pneumonia which coexists with pertussis are the same as those that prevail in a case of simple pneumonia, except that the respiration is accompanied by a peculiar expiratory moan.

Not long ago I attended a well-marked case of whooping-cough in a child five years of age who apparently was otherwise in excellent physical condition. The child seemed to get along very nicely, and appeared perfectly well between the paroxysms of coughing, but the temperature remained a little above normal, and the pulse was quite rapid. I could not account for this state of affairs till on auscultation I found the respiratory murmur very harsh and vesiculo-bronchial in character, with a diffused number of sonorous and sibilant rales.

I gave what I thought the proper treatment, but the temperature and pulse increased and dyspnea became more marked. After five days the breathing had lost its last vestige of softness and was entirely bronchial, and associated with it a number of small bubbling rales. I could not check the progress of the infection, and found I was confronted with a well-marked case of broncho-pneumonia. The child rallied along for over three weeks, but with little changes daily. I called convell, but the child died in the fourth week of her broncho-pneumonia.

In measles we are liable to the same lung complications as in whooping-cough, but in this disease pneumonia occurs as a sequel more frequently than in any other constitutional malady of early life. Complications may occur in measles at any period, but they commence most frequently in the first stages.

In a fatal case of bronchitis which I attended some time ago the respiration was unlike the ordinary from the start, and the little patient became so nervous that she could not remain quiet for a dozen seconds. The pulse after the first few days, instead of becoming slower, as is generally the case, became more rapid. Subcutaneous rales were very abundant, and the dyspnea increased so rapidly that the child died of suffocation at the end of the fifth day.

Pneumonia is very protracted and fatal in measles. It is usually of the lobular form. If the child recovers it generally leaves him weak and debilitated for some time to come, and prone to succeeding attacks. Professor J. Lewis Smith records a number of cases of pneumonia following measles in which the patients recovered from the first attack, but eventually they succumbed to the same lung affection inside of a few years.

Tuberculosis is a common sequel. It generally rises in the bronchial glands, which become enlarged during the progress of the disease. The glands offer a splendid field for the development of the germs. Consumption may also begin in some of the patches of broncho-pneumonia, and from these foci a more or less widely spread infection may start.

In scarlet fever the lungs are not so liable to become affected as in whooping-cough or measles. Still, the eruption may extend down the mucous membrane to the larynx to the trachea, or to the bronchi, giving rise to pneumonitis, pleuro-pneumonia, or emphysema, or possibly stir up some latent tubercle bacilli and be the beginning of pulmonary
tuberculosis. The treatment, therefore, should not only embrace that of the infectious disease, but also be directed to the prevention of various possible subsequent ailments.

It is not very long ago that the practice was common among the laity of putting their children, while they were still young, among other children suffering with acute infectious diseases, so that they would contract the disease, and not be liable to it when they grew older. But the parent could hardly have recognized the serious troubles which were very likely to result from this practice, leaving the child with a lessened power to resist or overcome the numerous maladies which are so liable to affect growing children.

The room in which the patient is confined should be entirely free from germs of any description. It would certainly be a reprehensible practice to allow a child with measles to remain in a room that was formerly occupied by a consumptive, as the bronchial mucous membrane is so inflamed from congestion as to offer a fruitful soil in which tuberele bacilli might begin their deadly work. The mucous membrane of the nose, mouth, and throat should be disinfected daily, and if we can only keep these parts thoroughly antiseptic, we are sure of preventing any further infection.

Vitiating air and overcrowding are two of the most important predisposing elements, especially in tuberculosis. Most mothers think that if they keep their rooms warm, be they ever so close, their greatest duty is performed. It is the physician's place to look after the ventilation, as, no matter how the rooms may be arranged, the air can be kept pure, wholesome, and free from contaminating germs. Impure air not only favors the distribution of bacilli, but lowers the nutrition of the patient and favors their development in the body.

The general health of the patient should be maintained if possible. This might be done by the use of a mild tonic, such as gentian, iron, or calumba. An excellent remedy, which is frequently used in the hospitals of New York, which builds up the constitution and does not disarrange the stomach, is the application of cod-liver oil to the chest. This is absorbed and acts as a food, besides being very soothing to the inflamed bronchial tubes.

One of the great difficulties in the way of successful treatment is the management of children during convalescence. When improvement is noticeable and health has partly returned, the child wearies of restraint, and seeks every opportunity to mingle and play with other children. The mother, sympathetic and affectionate, but unwise, seeks to be convinced that strength and health have returned, places no check upon the inclination of the child to romp and roam about, and by the very act—the prompting of love, no doubt—subjects the yet delicate little creature to many and serious dangers, such, for instance, as exposure to drafts, which not infrequently results in severe attacks of bronchitis or pneumonia. Parents or nurses should be made to appreciate the imprudence of allowing children to leave their beds before complete convalescence. If they refuse to be guided by the good words of advice given, they will then learn the lesson through the sad experience of the little one's death. It will then be too late for caution. Grief steps in and reigns.

ous, so that Freud stood almost alone as its champion. All that has been marvelously changed, and excision of the uterus is now practised with such frequency as to be almost an everyday matter; it is often done for diseases that practically do not tend to shorten life or to render it very burdensome, and it is sometimes done, we fear it must be said, for no other reason than that a not overconscientious practitioner wishes to be able to say that he has done it. This is true of almost all surgical operations, but they are not all so mutilating, they do not all put life in appreciable peril, and they do not all entail peritoneal adhesions. It can not be doubted that the uterus is often removed when it is still equal to the task of gestation, and when at the same time there is no real need of the operation.

In the installment of the proceedings of the recent meeting of the American Gynecological Society that we publish this week there will be found an interesting and wholesome debate on this subject. It is monstrous, we hold, to advocate excision of the uterus because the organ is affected with benign neoplasms that at most give rise to quite moderate trouble, and we are glad to find that Dr. Emmet, in the discussion referred to, cast the great weight of his opinion against it. There never was greater need of conservatism than now, especially as regards this particular operation.

MINOR PARAGRAPHS.

THE HARLEM HOSPITAL.

The stories that have lately appeared in some of the livelier of our newspapers implying declension of duty on the part of the medical staff of this hospital and the imminence of their dismissal seem to have resolved themselves into the simple fact that the commissioners of public charities and correction have determined that the staff shall be reorganized on the basis that prevails in the case of Bellevue Hospital — i. e., each of the three large medical schools to have a representative and the profession at large another. Such an arrangement may be proper enough in itself, but we do not think the commissioners will be acting in fairness toward the gentlemen of the present staff if they dismiss them in order to carry it out; it would be fair, however, to work into it gradually as vacancies occurred in the usual way.

CLEIDOTOMY.

Dr. Phænomenoff, of Kasn, in an article published in the Centralblatt für Gynäkologie for June 1st, recommends this operation in cases in which, after the fetal head has passed the brim of the pelvis, the shoulders are arrested and can not be so manipulated as to be made to enter the pelvic cavity. The procedure consists in cutting through each clavicle, together with the soft parts overlying it, with a strong pair of shears. This results in a notable lessening of the biseoronal diameter, and the shoulders soon accommodate themselves to the pelvic canal.

The University of Pennsylvania.—A portrait of the late Dr. William Goodell and a bronze bust of the late Dr. Joseph Leidy have been given to the university.

The Belgian Society of Surgery.—The Société belge de chirurgie has elected Dr. Louis A. Sayre, of New York, an honorary member as an acknowledgment of his great services to surgical science.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 9 to June 15, 1895:

Beechemen, Louis, Captain and Assistant Surgeon, will be relieved from duty at Columbus Barracks, Ohio, upon the return from leave of absence of Walters, William E., Major and Surgeon, and will proceed to and take station at Baltimore, Md., as attending surgeon.

Clark, Joseph T., Captain and Assistant Surgeon, is relieved from duty at Fort Omaha, Nebraska, and ordered to Fort Washakie, Wyoming, for duty, relieving Raymond, Henry L., Captain and Assistant Surgeon. Captain Raymond, on being thus relieved, is ordered to Fort Niagara, New York, for duty at that post.

Gardner, Edwin F., Captain and Assistant Surgeon, is relieved from duty as attending surgeon and examiner of recruits in Boston, Mass., and will report in person to Alden, Charles H., Colonel and Assistant Surgeon General, president of the examining board appointed to meet in this city, for examination by the board as to his fitness for promotion, and upon conclusion of his examination he will report for duty at Fort Grant, Arizona.

Maes, Lucas M., Major and Surgeon, is granted leave of absence for one month and twenty days, to take effect on or about August 10, 1895.

Perley, Harry O., Captain and Assistant Surgeon, will report in person to Alden, Charles H., Colonel and Assistant Surgeon General, president of the examining board appointed to meet in this city, at such time as he may be required by the board for examination as to his fitness for promotion, and upon conclusion of his examination will proceed to Hot Springs, Ark., and take charge as commanding officer of the Army and Navy General Hospital, relieving Woodhull, Alfred H., Lieutenant Colonel and Deputy Surgeon General. Lieutenant-Colonel Woodhull, on being thus relieved, will report in person to the Commanding General, Department of the Colorado, for duty as medical director of that department, relieving Huntingdon, David L., Lieutenant Colonel and Deputy Surgeon General. Lieutenant-Colonel Huntington, on being thus relieved, will report in person to the Surgeon General for duty in charge of the Museum and Library Division of the Surgeon General’s Office, relieving Billings, John S., Lieutenant Colonel and Deputy Surgeon General.
Richards, Charles, Captain and Assistant Surgeon, is relieved from duty at the United States Military Prison, Fort Leavenworth, Kansas, to take effect June 30, 1895, and will proceed to comply with the order for him to take station at St. Louis, Mo.

Richards, Charles, Captain and Assistant Surgeon, is granted leave of absence for three months, to take effect when he shall be relieved from his present duties, on or about June 30, 1895.

Town, Francis L., Colonel and Assistant Surgeon-General, is granted leave of absence for two months, to take effect about July 1, 1895.

Wakeham, William J., Captain and Assistant Surgeon, will be relieved from duty at Fort Thomas, Kentucky, upon the arrival there of Grason, Rorer J., Captain and Assistant Surgeon, and will report for duty at Fort Huachuca, Arizona, upon the expiration of the leave of absence granted him.

Wales, Philip G., Captain and Assistant Surgeon, now on temporary duty at Fort Niagara, New York, will return to his proper station upon the arrival of Raymond, Henry L., Captain and Assistant Surgeon, at that post.

Wyeth, Marlborough C., Captain and Assistant Surgeon, is granted leave of absence for two months, to take effect the latter part of August, 1895.

Pilcher, James E., Captain and Assistant Surgeon, will be relieved from duty at Fort Niagara, New York, upon the expiration of his present sick leave, and will report in person to the commanding officer, Columbus Barracks, Ohio, for duty at that station.

Promotions.

Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Fifteen Days ending June 15, 1895:

Perrviance, George, Surgeon. Relieved from duty at Philadelphia, Pa. (temporarily), and detailed for duty on board relating to Ford's Theatre disaster. June 8, 1895.

White, H. J., Passed Assistant Surgeon. Detailed as recorder of the board for physical examination of candidate for the Revenue-Cutter Service. June 1, 1895.

Coper, L. E., Assistant Surgeon. To inspect unserviceable property at San Diego Quarantine Station. June 12, 1895.

Cumming, H. H., Assistant Surgeon. Relieved from temporary duty at Boston, Mass., and ordered to rejoin his station at New York, N. Y. June 3, 1895.

Society Meetings for the Coming Week:
Monday, June 24th: Medical Society of the County of New York; Boston Society for Medical Improvement; Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

Tuesday, June 25th: Medical Society of New Jersey (first day Cape May); Medical Societies of the Counties of Essex (annual—Elizabethtown) and Lewis (annual), N. Y.; Buffalo Obstetrical Society.

Wednesday, June 26th: Medical Society of New York (second day); American Microscopical Society of the City of New York; New York Pathological Society; Metropolitan Medical Society, New York (private); Medical Society of the County of Albany; Philadelphia County Medical Society.

Friday, June 28th: New York Society of German Physicians; Philadelphia Clinical Society; Philadelphia Laryngological Society; Cleveland, O., Medical Society.
the symptoms rapidly disappear on the exhibition of fresh food or fruit acids the demonstration is practically conclusive. The disorder has been well described by Dr. William P. Northrup in the *Archives of Pediatrics* for January, 1892, and the *New York Medical Journal* for May 26, 1894, and by others.

The fact that scurvy in infants has only recently been recognized in this country, and the great importance of an early diagnosis, are my apology for this communication.

**Henry Ling Taylor, M. D.**

112 East 128th Street, New York, June 15, 1895.

To the Editor of the *New York Medical Journal*:

Sir: In his article, *A Case of Rickets with Exaggerated Mouth Symptoms*, Dr. H. D. White complains that he has been unable to find much allusion to such symptoms in any of his reference books. The reason is a very simple one. The fact is —I am sorry to say it—the doctor has been treating, not a case of rickets, but a most typical and characteristic case of infantile scorbutus.

The doctor says that the symptoms prominent in this disease (rickets) were all absent in this case, but what struck him forcibly was the hypertrophy and sponginess of the gums, and upon this—the most characteristic symptom of scurvy—he made a diagnosis of rickets. Well, errore humanae est.

The acuteness of the attack alone would point toward scurvy. As Cheadle and Barlow have demonstrated, and as Osler says in his *Practise* (page 311), “The disease known as acute rickets is in reality a manifestation of scurvy and will be described with that disease.” Add to this the acute severe pain in the lower limb, with the absence of deformity (in rickets there is only a diffuse soreness, and deformity is frequent), the sponginess and bleeding of the gums, etc., and the diagnosis of scurvy is established beyond the possibility of contradiction.

Some may say that the treatment was not antiscorbutic—no lemon juice, fresh vegetables, etc.—and the improvement was nevertheless rapid. In a discussion that took place after the reading of a paper, Scorbutus in Infancy, before the Medical Society of the County of New York on April 23, 1894, by Dr. W. L. Carr (see Medical Record, vol. xlv, pp. 812, 820), the majority of the gentlemen expressed the opinion that all that was necessary in the treatment of scurvy was good, nourishing, and varied diet. I remember hearing Dr. Joseph E. Winters say that his treatment of scurvy consisted in the use of cream, cod-liver oil, and beef juice—the same treatment that was followed in this case.

**William J. Robinson, M. D.**

**DIPHTHERIA ANTITOXINE SERUM.**

**Spill Lake, Iowa, May 27, 1895.**

To the Editor of the *New York Medical Journal*:

Sir: Prompted by the universal professional interest in the serum treatment of diphtheria, I will, if you please, report the following case—the only one in which I have used the antitoxine: I was called on April 5, 1895, to see a farmer’s little son, nine years of age, ill with membranous croup. This was at 10 A. M. on Sunday. On the Thursday preceding he arose not feeling well and somewhat hoarse, but went to school. Came home at noon, feeling worse and decidedly more croupy. He passed a bad night, and on Friday morning a physician was called. The usual remedies failed to give relief, and he continued very sick through Friday night and until Sunday morning, when I first saw him. At this time there was a good deal of cyanosis, with frequent attacks of chocking, respiration labored, and no voice above a whisper. I had a few days before obtained a bottle of Behring’s antitoxine, white label. With an ordinary syringe I injected the entire contents of the bottle, making five injections in order to do this with the small syringe at hand. I saw the patient the next day, and found him much improved. He had had no more choking spells, was breathing better, could talk better, had a decreased temperature, and was in every way more comfortable. A general utricaria had broken out, which gave some discomfort, but passed off the second day thereafter. From this time on improvement was uninterrupted, though the hoarseness persisted for a week or more. I have had recently five other cases of true croup, in all of which the patients died, under the usual approved methods of treatment; and so confident did I feel of the diagnosis and probable result in this case that I informed the parents at once that I entertained only the slightest hopes of the child’s recovery.

**Proceedings of Societies.**

**AMERICAN GYNECOLOGICAL SOCIETY.**

Twentieth Annual Meeting, held in Baltimore on Tuesday, Wednesday, and Thursday, May 28, 29, and 30, 1895.

(Continued from page 757.)

The President, Dr. Matthew D. Mann, of Buffalo, in the Chair.

The Use of Traction and Morsellation in the Removal of Fibroids vs. Hysterectomy.—Dr. Thomas Addis Emmet, of New York, read a paper with this title. He said that the method of treating fibroid tumors by traction and morsellation was not generally known to the profession, although he had practised it for many years. If this procedure was properly carried out, he believed that it would greatly reduce the number of total extirpations. Altogether too large a proportion of women remained invalids after total extirpation of the uterus. The most important fact to determine after locating a uterine tumor was the rapidity of its growth. The more rapid the growth, the more urgent the necessity for extirpation, irrespective of the amount of hemorrhage. Of course, the age of the patient would have some bearing in deciding as to the necessity of removing the uterus for fibroids. There was an undetermined proportion of women in whom the changes incident to the menopause exerted a favorable influence on the fibroids, but this number was sufficiently large to warrant the expectation that there would be at least some amelioration at this period of life. He could not, therefore, accept the position of those who favored the indiscriminate performance of hysterectomy for fibroid growths.

His method of operating in cases of uterine fibroids, although first performed as long ago as in the winter of 1861-62, was now coming back to us from abroad as a foreign operation. Ergot was of no value in these cases unless the tumor was so situated that gravity could assist, and unless the canal was kept freely open. He believed that the ergot acted on the muscular structure of the blood-vessels, and so cut off the blood supply to the tumors. For this very reason, this method of treatment had sometimes led to disastrous results. In his method of operating, the traction was to be made chiefly in the form of a lateral twisting movement, counter-pressure being made on the uterus. He regretted very much the abandonment of sponge tents, and expressed the opinion that our future advance would rest largely upon improvements that would admit of the more extended use of these tents.

In conclusion, he said that he believed that nearly all fibroids originated near the uterine canal, and tended to project finally into the uterine cavity.
Dr. W. M. Polk, of New York, opened the discussion. He said that the mortality rate at the present time from total hysterectomy for fibroids might fairly be stated to be only one or two per cent, if the operation was confined to suitable cases. He felt that all present had patients who had been so innumerably benefited by hysterectomy that the results fully compensated for the occasional untoward consequences that had been observed to follow this operation. For this reason, it was unfortunate that such a leader in gynecology as Dr. Emmet should take such an uncompromising position on this subject. The speaker felt that in operating in these cases of uterine fibroids the intraperitoneal route had been too much neglected, and he believed that in this direction lay the possibility of obtaining successful results at much less cost to the patient.

Dr. J. Montgomery Bailey, of Philadelphia, said that by total hysterectomy the patients were relieved of the symptoms due to the fibroids, although they undoubtedly suffered from the less important symptoms of the menopause. If we were to follow Dr. Emmet's advice and allow these tumors to go on, we should soon find many patients in such a condition that we should be compelled to refuse to operate. His own experience fully confirmed the views expressed by Dr. Gordon.

Dr. Paul F. Muxde, of New York, said that an experience of over twenty years had not led him to believe that it was justifiable to remove a uterine fibroid unless it produced symptoms by its pressure and rapid growth or caused profuse hemorrhage, or the patient insisted on an operation. If these patients were kept under observation, as they should be, they would not be allowed to reach an "inoperable" stage. On one occasion he had removed through the vagina a morcellation of a tumor weighing three pounds, and at another time, by the same method, and at one sitting, thirty-four distinct fibroids.

Dr. Howard A. Kelly, of Baltimore, said he heartily concurred in the views expressed by the last speaker, and he wished to express his entire disapproval of the position taken by Dr. Gordon. He would do total hysterectomy for tumors producing profuse hemorrhage or which caused severe suffering by their pressure.

Dr. H. S. S. Sutton, of Pittsburgh, said it was important to determine whether the tumor was a myoma or a fibroma, as there was so much difference between these two varieties of tumors as between an adenoma and an angioma. No one had ever seen a true fibroma disappear, although doubleless myomata had been observed to do so. The question of the social position of the patient—as to whether or not she must earn her living—also had an important bearing on the question of the most appropriate treatment for the individual case.

Dr. McGonigal, of California, said that if the ovaries and tubes were healthy, and the tumor could be removed, it was our duty to remove it without disturbing the integrity of the appendages. The submucous fibroids could, for the most part, be taken out through the vagina, while the subserous fibroids would ordinarily require to be removed from above.

Dr. A. Palmer Pedley, of New York, said that his experience had not agreed with that of Dr. Emmet regarding the tendency of the majority of submucous fibroids toward the interior of the uterus—he had found that most of them became subperitoneal. Sponge tents were an abomination, not only because of the danger of sepsis when they were carelessly made, but because of the difficulty of removing them. By lateral incisions into the cervix, the cervical canal could be sufficiently dilated without the use of dangerous sponge tents to permit of the removal of tumors weighing between one and three pounds. After the removal of the tumor, the cervix was to be sutured and primary union secured.

Dr. A. J. C. Steene, of Brooklyn, said that he had operated by Dr. Emmet's method over a hundred times, and the only death in this series had occurred in a woman who was already septic at the time of the operation. It was absurd to think of removing all the sexual organs when Dr. Emmet's operation was competent to deal with the condition.

Dr. George J. Engelmann, of St. Louis, said that he had seen a large number of these tumors, yet he knew of no way of distinguishing clinically between myomata and fibromata, or of knowing at the outset that this or that tumor would disappear. He hoped the society would not put itself on record as favoring the performance of hysterectomy for every fibroid tumor of the uterus.

Dr. Montgomery, of Philadelphia, said that tumors projecting into the uterine canal should be removed without disturbing the uterus. The subperitoneal variety might be enucleated and myomectomy performed, thus leaving behind a uterus functionally competent. Many cases demanded hysterectomy simply to enable the patient to earn her living.

Dr. Howard detailed two or three cases in which, while conservative measures had been employed to relieve the prostration the tumor had presented at the outset; and he had succeeded in extracting it through the vagina by traction and morcellation.

Dr. A. H. Buckmaster, of the University of Virginia, said that, as in many cases it was impossible to make an accurate diagnosis of an intra-uterine fibroid without dilatation of the cervix, such an exploration should invariably precede a resort to hysterectomy.

Dr. J. Riddle Goffe, of New York, said that a very small fibroid in a woman of thirty years might demand hysteroectomy, while a tumor of the same size in a person approaching the menopause might not demand such a radical measure. It was the rule for these tumors to diminish or disappear after the menopause.

Dr. Gordon said that he agreed with Dr. Emmet that such tumors as could be removed per vaginam should be treated by this method. He could not agree to Dr. Sutton's statement that the choice of the method of treatment should be influenced by the patient's social condition. Lest he might be misunderstood regarding his position on this important subject, he would once more clearly define it. In all cases where a woman found herself an invalid from a fibroid uterus to the extent of seeking the advice of a surgeon, unless such tumor could be successfully and easily removed per vaginam either by enucleation or by morcellation, conservative surgery demanded hysterectomy. In his experience he had found the abdominal method the preferable one.

Dr. T. A. Emmet said that for years he had been misrepresented as opposed to the removal of the uterus. There were certain cases in which one could say at once that the uterus should be removed. His main point was that no one should remove the uterus until the canal had been dilated, and a digital exploration had enabled him to form an intelligent opinion of the true position and condition of the fibroid tumor. If the canal was kept dilated and the patient under observation for some time, it would sometimes not be necessary to resort to a radical procedure.

Signature of the Pedicle with Catgut.—Dr. Archibald MacLaren, of St. Paul, read a paper on this subject. The catgut was prepared by a method of dry sterilization devised by Dr. Beckwith. It was cut into convenient lengths, wrapped in waxed paper to prevent burning, placed in envelopes, and kept in a sterilizer at a temperature of 290° F. for four hours. Numerous culture tests had proved that the catgut was thoroughly sterile, and, as it could be carried around in the pocket
in these envelopes, the method of preparation was particularly convenient. Catgut could be prepared in this way on a large scale by a manufacturer, as there was no danger of its being handled by incompetent persons. The author reported in his paper seventy-three abdominal sections in which nothing but catgut had been used for ligatures. There had been no deaths in this series that could be attributed to the catgut.

Dr. A. P. Decker said that he had used catgut since 1885 in a great variety of abdominal cases, and had not seen suppuration brought about by its use. He had at last found a firm in New York that could rely upon to prepare the catgut properly.

Dr. Polk said he had carefully prepared his cases, and had found that those in which he had used silk had done better than those in which catgut had been employed. The catgut had been prepared for him by no less an expert than Dr. Rice, yet it had sometimes given him trouble, and in these cases, strange to say, the bacteriological examination had thrown no light on the cause of the difficulty. Some of the worst catgut that he had ever used had come from the very firm that Dr. Dudley trusted so implicitly.

The President said that he had employed catgut quite extensively for the past ten years, and he could not say that he had ever seen any bad result that could fairly be attributed to it.

Dr. Kelly said that he had been led to abandon catgut during the past two years because of trouble with it. He had found that very fine silk possessed almost all the advantages of catgut without its uncertainties.

(To be continued.)

Book Notices.

In his introduction to the volume the author reviews the nomenclature of inflammation of the appendix, and concludes that the term "appendicitis" is too firmly established to allow of the substitution of "eperyphalitis"; still, as the symptoms resulting from this inflammation are due solely to the involvement of the peritoneum, he considers "appendicular peritonitis" a preferable term for the affection.

The work of Bichat, Laennec, Ferrall, Mestivier, Dupuytren, Goldbeck, Copland, Barne, Albers, Grislolde, Villierney, Volzt, Rokitansky, Lewis, Wister, Fitz, and others is reviewed and due credit given for the part each has performed in clearing up the subject of disease of the appendix.

The description of the anatomy of the appendix is based in part upon the author's original investigations and largely upon the researches of J. D. Bryant, Fowler, Treves, and Lockwood and Hollestone. The author believes that an extraperitoneal appendix is an anatomical impossibility. In a hundred bodies of all ages taken at random, in cases in which death had occurred from some other cause than disease of the appendix, a microscopic examination of that part showed evidences of past or present disease.

The author's division of appendicitis into catarrhal and ulcerative is accepted, to which the author considers that a third form, "infective appendicitis," should be added.

The author summarizes the affections of the appendix as:

1. Catarrhal appendicitis, marked particularly by shedding of the protective epithelium, apt to pass into a chronic condition with thickening of the wall.

2. The cystic condition of the appendix, whether due to a post-catarrhal stricture or to kinking.

3. Ulcerative appendicitis due to the presence of a focal connection or a foreign body.

4. Acute infective inflammation of the wall of the appendix, commonly associated with necrosis of its tissues; this may occur when the muco-erythelial membrane shows slight signs of chronic disease, but in the majority of cases it supervenes upon one of the foregoing conditions.

The pathology of each of these conditions is described at length, and the text is illustrated by a number of excellent drawings of microscopic sections. Tubercular, typhoid, and actinomyiotic disease of the appendix are but briefly mentioned.

For convenience, appendicular peritonitis is classified as general, local, suppurative, or adhesive, and each of these forms is described clinically, the author citing cases.

In the review of the treatment of appendicitis the author advocates the principles which were laid down by Bell in a paper published in this Journal in 1873.

The author believes that routine excision of the appendix at a very early period might save a few persons from general peritonitis, but he doubts whether the resulting gain of life would be large enough to counterbalance the disadvantages of the wholesale surgery which such a practice would entail; and he commends excision of the appendix after a first attack as a better measure than excision during the attack. While the author apparently inclines to the conservative treatment originally advocated by Bell and in vogue in England, he is greatly impressed by the evidence which has been presented by American surgeons, and it is apparent that he is simply waiting for time to substantiate their results in order to give the practice of early operation his sanction. The book is an interesting and useful contribution to the growing literature relating to diseases of the appendix.

The author makes a prefatory apology for his two and a half years' delay in the publication of this second volume of his work, due to the unexpected magnitude of the task of gathering together and classifying the numerous contributions which have been made to fetal pathology during the fifty years which have elapsed since Gnetzner's comprehensive work on the same topic. Any one who has undertaken a work of this character can appreciate the difficulty attending such investigations and the reasons for the delay. The author states that the vast amount of material he has collected indicated the impossibility of completing the work in the number of volumes originally selected, unless he considered the remainder of his subject in an imperfect and inadequate way; he has therefore wisely decided to discuss the questions fully and depart from the original limits of the work.

In this volume the consideration of the diseases of the sub-
cutaneous tissue is considered. The first four chapters describe selererna neonatorum, which is provisionally defined as a grave disease affecting the newborn infant, "characterized by indurations, and sometimes by edema, of the subcutaneous cellular tissue, and by lowering of the body temperature, and due possibly to some trophic lesion of the nervous system." The author considers that edema neonatorum, a symptom of several morbid states, is often confounded with selererna neonatorum, and that much confusion has been the consequence. The first recorded case of the disease was in 1718, and during the present century a number of cases have been reported, especially in France and Italy. All the theories of the pathogenesis of selerema are reviewed, and they demonstrate an unsatisfactory state of our knowledge; the diagnosis, prognosis, and treatment receive due consideration.

A chapter is devoted to subcutaneous abscess in the face, atrophy of the subcutaneous tissue, and dermatolysis.

The remaining eight chapters of this volume are devoted to those idiopathic diseases of the skin in which hyperkeratosis or keratolysis is the leading pathological feature. The author adopts a scheme of classification of congenital skin diseases founded upon the arrangement of cutaneous affections in general which was proposed by Auspitz and modified and elaborated by E. B. Bronson. Attention is directed to the fact that comparatively little has yet been accomplished in explaining the relation of the embryology of the skin to cutaneous diseases; and the author suggests that investigation of the epithelial changes in the human and other embryos may throw some light on the mode of origin of fetal ichthyosis, while the embryology of cutaneous pigment formation and the histological characters of navi are yet unknown.

This volume maintains the excellent standard of its predecessor, and the work marks an epoch in the literature of the subject of antenatal pathology.

The question of immunity is one of the most interesting problems in medicine, and the result of all the time and care which have been bestowed upon its investigation is summed up by the author of this volume in the conclusion that natural immunity is due to a germicidal substance present in the blood serum which has its origin, chiefly at least, in the leucocytes and is soluble only in an alkaline medium. He holds that local infection is usually resisted by an afflux of leucocytes to the point of invasion, but that phlegmocytosis is a factor of secondary importance in resisting parasitic invasion. He further holds that general infection, at least in some infectious diseases, is resisted, and in non-fatal cases overcome, by an increase in the number of leucocytes and in the alkalinity of the blood serum which favors solution of the germicidal proteins contained in the multinucleated leucocytes.

Experimental evidence is cited to show that acquired immunity is due to the presence in the blood of some substance capable of neutralizing the toxic products of the particular pathogenic micro-organism against which immunity exists, or of destroying the germ itself, and this substance is called an antitoxin. What the method of production is and what is the exact source of the antitoxin in the animal body is unknown. The discovery of the anthrax bacillus and Tousanj's publication of his method of producing immunity by protective inoculations of sterilized cultures was followed by Pasteur's discovery of the method of attenuating the virulence of the anthrax bacillus and his method of inoculation with progressively virulent cultures. The history of anthrax as well as of chicken-cholera inoculations is fully narrated.

A chapter is devoted to the history of Ferran's and of Haffkine's methods of producing immunity against cholera by inoculations of sterilized cultures, but the author doubts if they will come into general use as a measure of prophylaxis against a disease that may be prevented by properly applied sanitary measures.

The literature of the antitoxine-serum treatment of diphteria is briefly reviewed, and attention is directed to the fact that the serum does not destroy the diphteria bacilli, relieve suffocation due to laryngeal obstruction, or cure acute parenchymatous nephritis due to the toxin produced by the Klebs-Loeffer bacillus.

The literature of protective inoculation for glanders, hog-cholera, hog-sey-spleen, rabies, influenza, pleuropneumonia, pneumonia, small-pox, swine-plague, streptococcus infection, symptomatic anthrax, tetanus, tuberulosis, typhoid fever, and yellow fever is reviewed in like manner.

The book is a satisfactory résumé of the very greatly scattered literature relating to these interesting subjects, and will be of great convenience to all who wish to know the present status of protective inoculation against any communicable disease.

This work is intended to be a handy manual for students preparing for their final examinations in medicine, and is a supplement to the well-known treatises on medicine rather than a text-book. While it was originally intended as a companion to Keeley's Index of Surgery, the author found that an alphabetical arrangement of the nomenclature of diseases would entail so many and such complex cross-references that the work would be disjointed and useless; so he abandoned the plan.

The general features of disease are considered in an introductory chapter, which is succeeded by one on general pathology; the consideration of general diseases, including specific fevers, then follows, with subsequent sections on the diseases of the different organs and systems. Each disease is defined, the predisposing and exciting causes are referred to, the symptoms are described, the complications and sequelae are mentioned, and the diagnosis, prognosis, and treatment are succinctly reviewed. No attempt is made to describe the diseases of the skin or those of the eye, ear, nose, or throat.

The author has accomplished his work with great thoroughness and has omitted no important detail. The volume is consequently an excellent one for the purposes intended.

In compliance with the wishes of some influential friends, the author has prepared this abridgment of his five-volume work on physiology, the final volumes of which were recently reviewed in this journal. He has accomplished the curtailment by omitting all histological matter and all discussions which might be considered of a too theoretical nature. What we have said in commendation of the former edition applies to this volume, and the fact that the cost is materially lessened by including
Drifting in Ethics.—At the recent meeting of the American Academy of Medicine Dr. Leartus Conner, of Detroit, read a paper entitled Drifting; Who, How, Whither? We extract the following passages from reliance sheets of the Bulletin of the American Academy of Medicine:

The first extensive revolt against the written law under consideration occurred in New York. It was preceded by an extremely bitter conflict and caused not a few ripples in the American Medical Association. The result of this revolt was that the friends of the written law established the New York State Medical Association and retained their allegiance to said law, while the opponents captured the old State society, abrogated the written and returned to the unwritten law. To many this seemed a revolutionary proceeding, but when it is remembered that the revolting faction simply returned to the first principles of the medical profession, principles which satisfied the profession during thousands of years, the matter assumes a different aspect. The reformers only abrogated the written law of 1817, preferring the larger individual liberty of the profession anterior to that date. Previous to this, Massachusetts had a contest along similar lines, which resulted in affording sectarian equal rights with regulars and turning popular prejudice against the medical profession.

The Mississippi Valley Medical Association gives its members entire freedom in the matter of consultations. Other medical societies, in various places, have taken similar action, notably in Chicago, Cleveland, etc.

An extensive knowledge of the habits of prominent physicians leads to the conclusion that a fat consultation fee is rarely refused because the attending physician is a sectarian. Personally the writer has often been told by colleagues that he was a fool because he regarded it a matter of gentlemanly honor to obey the spirit and letter of the law of consultations while he retained membership in societies having this law as a condition of membership.

Another marked illustration of this drifting was seen when a committee of its own appointment reported to the American Medical Association that it favored such alteration of the code of ethics as would permit consultations between all physicians properly educated, legally qualified to practice medicine, and of honorable reputation in the place where they lived. When it is remembered that the committee so reporting individually obey both the letter and spirit of the code bearing upon this point, it will be evident that their report indicates a drifting of the medical profession.

This drifting is further seen in that regulars and sectarians work side by side on boards of health, State and local, and on boards of other State institutions. This very imperfect sketch shows that, whether we like it or not, the fact cannot be disguised that the professional relationships of regulars and irregul

MISCELLANY.

the most honorable, and the workers receive the largest returns in money, honor, and fame.

Whither does this drifting tend? The history of the past and the logic of existing social forces point to but one result—viz., the absorption of all ideas that are true and helpful, and all persons who are honest and of good report, into the medical profession. To this end larger liberty will be accorded the individual physician. He will be permitted to choose his professional associates from among those whom he knows to be properly educated, legally qualified to practice medicine where they reside, and of good report. Qualifications other than these will be regarded as purely local in their necessity and temporary in their existence, and to be controlled entirely by the individual physician. It was wiser to object to consultation with a physician because of known ignorance, lack of skill, dishonest methods, or disgusting character, than because of his sectarian name. Objection on the first ground is readily understood by any layman, but objection on the second fails to commend itself to most persons, and not infrequently brings the objecting physician into disreputable.

797

and aimlessly and making less noise. He appeared unable to
clear his throat of mucus, and the ery at the end of expiration
seemed to indicate pain. Later, he became more quiet, and his
pulse was counted at 150. Pinching his limbs excited cries of
pain, but not much movement. The pulse remained very
feebly, and cold perspiration continued. The breathing was
quiet, but rattling. He was apparently asleep, but pinching
did not rouse him. At 10 a.m. he was still comatose and
could not be roused to answer questions. He was sick and
weak. The pulse was 120 and feeble. About half an hour
later he regained partial consciousness, but was heavy and
stupid all day. The urine passed was found to be very dark
in color from absorption of carboolic acid. On August 29th the
patient still felt sick, and vomiting occurred now and again.
He was very thirsty. The pulse was 126 and the temperature
101° F. His breathing was quiet. In the evening his tem-
perature rose to 103° F. On August 30th his temperature at
10 a.m. had fallen to 100° F. Sickness occurred occasionally.
On August 31st the sickness ceased. The patient had a hectic
flush on each cheek. He felt much better. The temperature
was 99° F. On September 1st he was feeling quite well.
On September 3d it was again arranged to operate, and a short
time before some five per cent., solution of carboelic acid was
applied on lint to the thigh. Soon he was noticed to be sick
and shivering, and his skin was bathed in perspiration. His
temperature was only 95° and his pulse scarcely perceptible.
He was stupid and answered questions with difficulty. The
operation was in consequence postponed, the compresses re-
moved, and the skin of the thigh thoroughly washed with
warm water. Subsequently for two days his urine was dark
from the absorption of carboelic acid.

A boy, aged six years and a half, was admitted under the
care of Mr. Lane on January 30, 1895, suffering from a swelling
in the right iliac fossa, which it was proposed to explore on the
following day. The dressing applied to the skin over and in
the vicinity of the mass a compress moistened with carboolic liont
(1 in 20). This was done at 12.20 p.m. At 1.30 p.m., after it
had been in position for an hour and ten minutes, the sister of the
ward heard the child groaning, and on examining him was
so alarmed that she sent at once for the house surgeon. On
his arrival a few minutes later he found the boy pale, collapsed,
and comatose. There was marked dyspnea, with convulsiv-
tsweekings of the eyelids and limbs. The pulse was 130, feeble,
and intermittent; the respiration was 72, and the temperature
97° F. Ether and atropine were injected hypodermically and
brandy given by the rectum. The patient was wrapped in
blankets and hot bottles were applied. The interrupted cur-
cent was also used. After this his condition became somewhat
less alarming, his pulse improving in character and his respira-
tion being less labored. At 3 p.m. the pulse was 150 and the
respiration 72. The eyelids still twitched and the tetanic con-
tractions of the muscles of the forearm and hand continued.
The pupils were dilated and reacted slightly to light, the face
was flushed, the lips less livid, and the body was covered by a
profuse perspiration. The skin at this time showed no sign of
having been irritated by the carboolic lotion. At 4.30 p.m. the
pulse was 146, much stronger, and the respiration was 72.
The twitching of the eyelids had ceased, together with the diffi-
culty of breathing, though the respirations were still abnor-
mally shallow and rapid. The patient had been perspiring
freely since the last observation. At 6 p.m. the condition of
the pulse and respiration did not differ from that observed at
4.30 p.m. The patient was still perspiring, and he screamed a
good deal and appeared to be regaining consciousness. He
vomited some dark fluid, which appeared to be imperfectly
digested beef tea, after which he seemed much relieved. At
7.30 p.m. the patient was quite conscious and talked quite
rationally. The pulse was 120, full and strong, the respira-
tion 32, and the temperature 98° F. He had vomited several times
since the last observation. He passed some urine which was
very dark green in color, distinctly acid, having a slight de-
posit of urates, but containing neither albumin nor sugar. It
gave the ordinary reactions for carboelic acid and its products in
urine. He continued to vomit at intervals until the afternoon
of the next day. He passed some more urine in the morning of
the same character as the last. The respirations fell in fre-
cquency to 24 during the night, his pulse not changing. On
February 1st, at 2 a.m., his temperature was 99° F., and at 6
a.m. it was 98° F. Although on February 2d the child seemed
fairly comfortable except for a little exhaustion, possibly con-
sequent on the vomiting, yet it was several days before he was
restored to his original condition of health. It would seem
probable that, but for the prompt action of the house surgeon,
Mr. D. M. Beddoc, the child's condition might have become
much more serious than it did.

With regard to the treatment, says Mr. Lucas, the first indi-
cation is to thoroughly wash the skin to which the carboelic
lotion has been applied to prevent any further absorption, and
next to treat the collapse. Hot bottles and warm blankets to
the surface, with warm brandy enemata and the subconscious
injection of ether, are the best means for this purpose. Strych-
nine or atropine may also be of service. In spite of the alarm-
ing and persistent nature of the symptoms, says Mr. Lucas,
their experience would lead them to give a favorable prognosis
if the cause were recognized sufficiently and means at once
taken to prevent any further absorption. That the absorption
was by the skin in both cases, there can be no doubt, he says,
for in the first case there were only three small sinuses open
and in the second case the skin was unbroken.

The Analysis of Voluntary Muscular Movements by Cer-
tain New Instruments.—In No. 345 of the Proceedings of the
Royal Society there is an abstract of an article on this subject
by Dr. William R. Jack, in which the writer says that the ob-
gect of this investigation was to determine the greatest speed
of which the voluntary muscular movements were capable, and
how far the speed was influenced by age and education.
Twenty-three normal and two pathological cases were exam-
ined. The normal cases were divided into three classes: per-
sons of special manual education, those of average manual
education, and those of inferior manual education, in whom the
hands were accustomed only to coarse movements and in whom
the fingers had had no special training. The ages varied from
eighteen to sixty-two. While the tracings were being made the
hand rested on a little table at the height of the recording
slide. It was found that the velocity of the more complicated
movements could be increased to some extent by practice.
Full details of the velocities attained in each case are given in
the original essay; in this abstract, says the writer, only a
statement of results attained will be made.

Beginning with the influence of training upon the velocity of
the movements, the pen movement was first studied, and the
rate at which a distance of three centimeters in the middle of
the slide was traversed was taken as the standard of compari-
son. Unfortunately, no tracings of this movement were taken
from musicians, but, on comparing the average of the tracings
derived from those of average and those of inferior manual
education, the following conclusions were arrived at:

1. That in those of inferior manual education (whose two
hands were both untrained) the velocity is equal in both hands
(3.4°-157 for the right and 6.5°-117 for the left hand).

2. That in those of average manual education the velocity
1. That the decrease in velocity is less marked than in the case of writing.

2. That the velocity is greatest between the ages of twenty and twenty-nine.

3. That the difference in the rate of decrease between the educated and uneducated classes is not so marked as in the case of writing.

With regard to finger movements, it was found that they retained nearly the same velocity for all classes between the ages of twenty and fifty, and that in the case of a man over that age, a laborer, there was a decided decrease. In the two pathological cases, one of lateral sclerosis in a man of forty-one and one of tremor of the hands following syphilis, in a man of fifty, similar results were obtained. The complex movements of writing were most seriously retarded, the pen movements less, and the finger movements least of all.

It appears then, says the writer, that as a movement increases in complexity, and involves in its performance the associated action of a greater number of muscles, its velocity diminishes, and the influence of education becomes more distinctly manifest. And as complex movements require a longer education for their rapid performance, so they appear to become sooner defective than the simpler movements. For it is in writing that the retarding effect of age is most apparent, while it is least so in the finger movement.

In the second part of the investigation it was desired to obtain tracings from a larger series of contractions than could be registered upon a microscopic slide. For this purpose an instrument was adopted consisting of a long steel bar held firmly in an iron clip, and carrying in a clamp, attached to one end, a smoked-glass plate six inches square. It was set in motion by an electro-magnet through which the current passed from a storage battery, and, as determined by the chronograph, it made fifty-four double vibrations a second. At Professor McKendrick's suggestion it was determined to investigate with this instrument the phenomena of fatigue. For this purpose Mosso's ergograph was adapted to the instrument, the recording part of which could be pulled on rails slowly away from under the registering lever, which worked up and down with the movement of the weighted finger. Thus a series of contractions and relaxations, divided by the oscillations of the bar into fifty-fourths of a second, was registered on each plate. The plate could be taken out and a new one substituted beneath the lever without stopping the movement of the finger. A key was interposed in the circuit to shut off the current while the plates were being changed.

Four normal and two pathological cases were investigated, series of tracings being taken with a half-kilogramme, a one-kilogramme, and a two-kilogramme weight. They show, says the writer, in a very striking manner the diminution in height of the contraction, and the coincident diminution in its velocity, due to fatigue.

The measurements which were taken of the rates of velocity at different parts of the tracings afford somewhat varying results, and the number of cases is too few for any definite conclusions to be drawn from them. But it would appear that while the diminution is gradual and uniform in the case of small weights, in that of larger weights it occurs, as a rule, more rapidly, and that the rate of diminution does not remain the same throughout the tracing.

The Treatment of Croup by Calomel Sublimations.—This method of treatment is described by Dr. Henry Fruitnigh in the Archives of Pediatrics for June. As to its rationale he does not attempt to express an opinion. The treatment should
be instituted as soon as the symptoms of croup appear. From five to twenty grains of calomel are used at intervals varying from half an hour to three hours, according to the urgency of the symptoms. In the average case the proper dose is fifteen grains, repeated hourly. The child is placed in a tent where the calomel is slowly sublimed. The treatment is continued from one or two days to ten or twelve days. The unfavorable symptoms which must be guarded against are salivation, diarrhoea, and depression accompanied by anemia. The author reports but one case of salivation among a large number of cases. Diarrhoea also is rare, and readiness is readily overcome by stimulants. The sublimations are not discontinued after intubation. While the author does not make extravagant assertions for the treatment, he is fully convinced that many children are rescued from death by croup by its use, and believes that he can never be induced to discard so potent and efficacious a therapeutic measure. The doses employed and the frequency of their application are somewhat greater than those advised by some authors. The efficacy of the treatment has come to be almost universally recognized in New York.

What is Croup?—In an article under this title, Dr. Henry Dessau, in the same journal, attempts to define the exact meaning of the term croup. Several disorders which vary widely in their nature are called croup. Laryngitis-mus striulitus and catarrhal laryngitis are the commonest of these. The first is practically a manifestation of ricketts and is in no sense croup. It often appears as the holding-breath spell of rickety infants, in which the face becomes livid, with perhaps convulsive twitching of the muscles of the face, followed by a loud crowing inspiration. Catarrhal laryngitis, or false croup, appears in two forms, the spasmodic and the simple. The spasmodic comes on suddenly at night, awaking the child out of sleep, and rarely occurs in children under a year old. Its most prominent features are a loud metallic ringing quality of the cough and alarming dyspnea. The simple form of laryngitis develops gradually with hoarseness and a ringing tone of the cough. It may begin during the day, but becomes more marked at night. There is usually elevation of temperature, and frequently there are attacks of difficult breathing. The voice is never completely lost. It is very difficult to distinguish this form of laryngitis from true croup. When the germs of diphtheria or pseudodiphtheria have been engratified upon such a laryngitis, the case presents many difficulties in diagnosis. According to a recent report of the board of health of New York, out of two hundred and eighty-six cases of so-called membranous croup, eighty per cent. showed the germs of true diphtheria, fourteen per cent. showed those of pseudo-diphtheria, and six per cent. were doubtful. In true croup the onset is usually insidious. The voice, at first hoarse, is gradually lost. The cough, at first metallic, soon becomes smothered. Attacks of dyspnea begin at long intervals, but the intervals soon become shorter and irrespective of day or night. All the signs are progressive in character. The diagnosis should be made if possible by bacterial examination. The term croup should only be applied to a pathological stenosis or narrowing of the calibre of the larynx from the deposit of an exudation or false membrane upon its mucous surface. It is due to diphtheria in such a large proportion of cases that every case should be regarded as one of diphtheria unless definitely proved to be something else.

The Eighth Edition of Martindale's Extra Pharmacopeia.—In a review of this book in the June number of the American Journal of Pharmacy Mr. Joseph W. England says that, while it is largely based on the British Pharmacopeia and the procedures of British pharmaceutical practice, it refers as well to the products and preparations of the United States Pharmacopeia. The work has a national reputation in Great Britain, and presents many features of interest to all pharmacists.

With regard to some of the formulas, says Mr. England, reference is made on page 128 to the "A. C. E. anesthetic mixture" of alcohol (sp. gr. 0'938) one volume, chloroform (sp. gr. 1'497) two volumes, and ether (sp. gr. 0'755) three volumes, that found favor in this country some years ago. This mixture has been condemned, he says, by American surgeons, on the ground that its rate of volatilization is unequal, so that the anesthetic patient is subjected to varying vapors, and not to an anesthetizing vapor of uniform composition. Mr. Martindale has recognized this fault, and maintains that it may be obviated by using the following formula: Absolute alcohol (sp. gr. 0'755) one volume, chloroform (sp. gr. 1'497) two volumes, and ether (sp. gr. 0'720) three volumes. He presents the results of experiments in support of this statement, which show a practically uniform rate of evaporation. The mixture has a specific gravity of about 1'01. Prepared with United States Pharmacopeia absolute alcohol, chloroform, and ether, the mixture would have a slightly lower gravity.

It is singular, says the writer, to note the influence that water in ether has of retarding anesthesia. He has frequently observed that the higher the specific gravity of an ether, the greater the amount of it that was required to produce anesthesia. To a degree, the higher the gravity of ether, the more water it contains, and it seems reasonable to believe that it is the presence of water in ether and not so much the alcohol that retards anesthetization, or rather renders an increased amount of ether necessary to produce it. That this is Mr. Martindale's opinion also, is evident from his improved formula for the "A. C. E. mixture," in which he seeks to minimize, as far as practicable, the percentage of water present, by using absolute alcohol, and an ether stronger than that contained in the original formula. This "A. C. E. mixture" is alluded to be safer than chloroform and quicker in action than ether, though not so quick as chloroform, and the improved formula certainly deserves a thorough trial.

If petrolatum possesses therapeutic virtues—which, apart from its being demulcent to the mucous membrane of the alimentary canal, is doubtful—a formula for an emulsion of it with hypophosphites is given on page 391, as follows: 

$\text{100 gr. petrolatum, } 331, \text{0z. av.; powdered acacia, 25 gr. av.}$

Mix and add four fluidounces of water. Dissolve a hundred and twenty grains each of sodium hypophosphite and calcium hypophosphite in six fluidounces of water. Add to the above with constant titration, and then add a sufficient quantity of water to measure fifteen fluidounces. Dose, from one to four teaspoonfuls.

In the making of tincture of strophanthus, Mr. Martindale gives preference to Fraser's process as improved upon by himself (i. e., exhausting the ground and dried seeds with ether, drying and exhausting with alcohol), to the United States Pharmacopeia process of simply percolating with a diluted alcoholic menstrum (alcohol 650 c. c. to water 350 c. c.) without prior exhaustion with ether. In the writer's experience, Mr. Martindale's process is decidedly the better of the two. It may require a longer time than the present United States Pharmacopeia process; but the final product is surer of representing all the therapeutically active principles of the drug.

Mr. Martindale refers interestingly to terebene on page 410, and says that, chemically, it consists of camphene, cineene, borneol, and terpenes, the last named of which is said to be the active or toxic constituent of terebene.

The United States Pharmacopeia for 1890 states that tere-
The Treatment of Burns with Thiol.—In the May number of *La Clinique* there is an article on this subject in which the writer says that according to A. Bilder, of Berlin, thiol is one of the best applications in the treatment of burns of all degrees. Bilder first washes the burned part with a weak solution of corrosive sublimate and then removes the cuticle hanging loose as the remnants of ruptured blisters, taking care not to touch those of which the walls are still intact. After dusting the burn with powdered boracic acid, the entire surface of the burned region and the healthy skin around it are painted with a solution of equal parts of thiol and water; finally, a layer of greased cotton is laid on the burn and kept in place with a bandage. Thiol allays the pain very rapidly and arrests the hyperemia of the skin. Part of the contents of the blisters is absorbed and the rest becomes dry in the form of semi-transparent, amber-colored crusts which are easily detached, leaving a completely healthy skin. At the end of eight days the dressing is removed. The rapidity of the cure varies according to the degree of the burn. In burns of the first and second degrees it is generally rapid. In those of the third degree the blisters which are formed under the dressing of thiol are smooth and show no tendency to retraction.

Grippe in the Puerperal Condition.—At a recent meeting of the *Congrès de la Société obstétrique de France*, a report of which appears in the *Progrès médical* for May 25th, M. Queirel, of Marseilles, reported thirty-five cases of grippe occurring in puerperal women. In all the cases there had been pulmonary localizations, and in two broncho-pneumonia. No deaths had occurred. Eleven of the women had been confined before term and the others at term. The membranes had been ruptured four times during the efforts made in coughing. One patient, who had undergone symphysiotomy, had been attacked with pneumonia during her lying in; another had had gastric symptoms and her child had erysipelas. There had not been a single case of suppuration. M. Queirel had used corrosive sublimate for vaginal and uterine injections, but he did not practise the uterine injections unless the temperature rose. Perhaps it was owing to this procedure that no cases of infection had occurred.

M. Gaullard had also had an epidemic of grippe in his clinic at Lille, but, he said, he had taken no particular care in regard to the genital organs; he had simply used antipyrine and in three or four days the patients had recovered. M. Queirel said that he had observed particular syndromes. In certain cases there had seemed to be an outbreak of small-pox; in others, angina, etc., but there had never been anything observed affecting the genital organs.

The Inundated Districts in France.—The *Progrès médical* for May 18th says that the sub-commissioners of the board of health who visited the localities where the recent catastrophe at Bouzy occurred reported that hygienic measures had been well and rapidly executed and that, at present, there was no danger to the public health. However, the board, having learned that several cases of sickness had occurred at Bouzy among those who had been so imprudent as to use the water from polluted wells, urged the necessity of absolutely forbidding the use of water from any of these wells. The prefect of the Department of the Ysoges went to Nomexy, where an epidemic was feared in consequence of the choked-up condition of the region and of the houses, in order to give an accurate account of the place and of the execution of the work of improving the sanitary condition. He afterward visited Bouzy, Chaumousey, Sancehy, Uxegney, and Domèvre, and everywhere he found that hygienic measures had been rigorously carried out.
The Knee-jerk in Diagnosis.*

By William M. Leszynsky, M.D.,
Lecturer on Mental and Nervous Diseases;
Neurologist to the Demit Dispensary, etc.

It was at first my intention to read a short paper on
some of the more prominent objective signs of structural
disease of the nervous system, but as the time allotted to
me is necessarily limited, I have concluded to confine my
remarks to a consideration of the knee-jerk and its signific-
ance in diagnosis. As our knowledge upon this apparently
circumscribed topic has materially increased within the
last few years, and as numerous valuable and interesting
clinical observations have been added to our store of infor-
mation, it would hardly be practicable, under existing con-
ditions, to even attempt to enter into an elaborate study of
this subject. I will therefore be as brief as is consistent with
truth, and only dwell on some of the more common
factors to be considered, and trust that the discussion may
call forth some of the points that may have been omitted.

The accompanying diagram represents a transverse sec-
tion of a segment in the lumbar region of the spinal cord,
and will serve to elucidate the text.

Primarily, the knee-jerk depends on the integrity of
the reflex arc situated in the third or fourth lumbar seg-
ment. When the quadriceps tendon is struck, the sensory
impression is carried backward through the sensory nerve
fibres A to the posterior nerve roots B, thence traversing
the posterior column C to the multipolar ganglion cell, D in
the anterior horn of gray matter. This constitutes the
sensory portion of the arc. The impulse is then projected
forward through the anterior nerve roots E and the ante-
orior crural nerve F to the quadriceps, thus producing a con-
traction in this muscle. This constitutes the motor por-
tion of the arc. The reflex centre in the cord receives
fibres G from the cerebro-spinal portion of the motor tract,
which serve to control its activity. It is assumed that
these fibres originate in the cerebral cortex.

While this description should not be accepted as anana-
tomically accurate, yet for all practical clinical purposes
this subdivision of the reflex arc and its inhibitory fibres
will prove satisfactory as a working hypothesis.

Method of Eliciting the Knee-jerk.—The ordinary and
customary method of testing the knee-jerk while the per-
son's legs are crossed may suffice when the knee-jerks are
active. Under such conditions the position of the limbs is immaterial. The utmost care, however, is
necessary when there is any doubt as to the character of
the action. Under such circumstances it is advisable to
place the patient sitting upon a high chair or upon the
edge of a table, so that the feet are free from the floor.
As a rule, both knee-jerks should be tested. Occasionally
much patience is required in satisfactorily determining
whether the knee-jerk is present or absent. In many in-
stances the anticipation of the tap upon the patellar tendon
occasions involuntary rigidity of the flexor group of mus-
tles, thus bringing to bear sufficient opposing force to
overcome the action of the quadriceps. Before and during
the examination the patient should close his eyes, and his
attention should be diverted from the purpose of the ex-
aminer either by conversation or rapid interrogation. Or
he may be directed, to make some muscular effort with the
hands, such as forcibly interlocking the fingers or elevating
the arms, etc. With this object in view any other similar
expedient may be resorted to that suggests itself to the
examiner. It is never safe to say that the knee-jerk is ab-
sent unless repeated and varied tests have been made with
the clothing removed. The well-established principle that
faulty methods in examination, like false premises in rea-
soning, result in erroneous conclusions, finds daily exem-
plification in the investigation just mentioned.

Not long ago, during a pleasant conversation with a well-
known practitioner, the subject of the diagnostic importance
(or, as he preferred to term it, the unimportance) of the knee-
jerks was touched upon. His conclusions were, that its
absence indicated locomotor ataxia, and its exaggeration,
sclerosis of the lateral columns of the cord. This is a fair
illustration of the limited knowledge upon this subject
possessed by a large majority of physicians throughout the
country.

While confining my remarks to this particular symp-
tom, let me state at the outset that the presence, exagger-
ation, or absence of the knee-jerk in itself is not sufficient
for a diagnosis without corroborative signs. In other
words, its exaggeration or absence per se is not pathogno-
monic of any special type of disease.

The absence of the knee-jerk is of more positive value
than its exaggeration. Any interruption or interference

* Read at the meeting of the Harlem Medical Association, May 1,
1895.
with the integrity of the reflex arc will abolish it. The obstruction may be either in the sensory or motor portion.

1. Thus, a lesion which involves the posterior roots of the posterior columns in the region of the second, third, or fourth lumbar segments, such as tabes or transverse myelitis, produces a break in the sensory path, and the knee-jerk is abolished. These are the only lesions in the sensory tract of the cord that are known to cause a loss of the knee-jerk.

2. A lesion involving the motor portion of the reflex arc, such as acute or chronic anterior poliomyelitis, or multiple or isolated peripheral neuritis affecting the anterior spinal nerves, will also abolish the knee-jerk.

The perplexing question naturally arises, By what method are we to determine the cause of the loss of the knee-jerk in an individual case? Excluding the very remote possibility of its being a physiological anomaly, we interpret its significance only after a careful study of its association with other symptoms. I have tested for the knee-jerk nearly one thousand children over three years of age, and found it present in every case. In fifteen its presence was somewhat doubtful at first, but was ultimately demonstrable.

1. Loss of the knee-jerk associated with severe, sharp, circumscribed, paroxysmal pains in the lower extremities; incontinence or slowness in emptying the bladder, with preservation of muscular resistance, with or without incoordination, with or without objective sensory symptoms, is indicative of organic changes in the lumbar segments of the cord, such as tabetic degeneration or a lesion of their posterior nerve roots.

2. Loss of the knee-jerk associated with diminished muscular resistance or evident paresis or paralysis in the lower extremities, pain in the course of nerve trunks with tenderness on pressure, some atrophy and quantitative decrease in faradism irritability, with or without objective sensory disturbances, and the absence of bladder symptoms, is a clinical picture of multiple neuritis.

3. Loss of the knee-jerk with faecid paralysis, atrophy, and loss of faradism reaction in the quadriiceps, and the absence of all sensory symptoms, indicates a poliomyelitis in the lumbar portion of the cord upon the same side.

Now, do not let us assume that the knee-jerk is completely absent in all cases of tabes. In some, the degeneration may begin in the cervico-dorsal portion of the cord, and, while symptoms such as ataxia, fulminating pains, anesthesia, and parasthesia are limited to the upper extremities, the knee-jerks may remain well marked until late in the disease, when the pathological process attacks the lumbar cord. I have seen a number of cases of tabes where the absent knee-jerk was unilateral. In one instance the patient was a man fifty years of age, who suffered extremely from the frequent and severe paroxysms of pain. He was under my observation nearly six years, but the knee-jerk persisted on one side. He died suddenly of cerebral hemorrhage. No autops}
s of both lower extremities. As the clinical manifestations and a confirmatory bacteriological examination are sufficient evidence of the disease, we should be unwilling to lay much stress on the importance of the absence of the knee-jerk as a factor in diagnosis.

I have seen three cases of meningitis in which the knee-jerk was absent in the early stage of the disease. A boy eight years of age was admitted to the hospital complaining of occipital headache of four days' duration. He had vomited once on the day of admission. A quarter of a grain of calomel was administered every half hour until the bowels acted thoroughly. I saw him two days later. Headache continued. There was slight tenderness over the occiput. Rectal temperature, 102° F. Pulse, 100, and regular; respirations 24. No vomiting. Pupils and ocular fundi normal. No hyperesthesia. There were neither physical signs nor evidence of infectious fever to account for the symptoms. Both knee-jerks were absent. This was a valuable sign, as it was known that they had been present. Provisional diagnosis of meningitis. Within thirty-six hours, headache increasing to stupor, rigidity of neck muscles, headache. Temperature, 103°. Nystagmus and hiccups pulsilis. It was then learned that he had fallen and struck the occipital region about a week before admission, but was not rendered unconscious at the time. Diagnosis, convexity meningitis of traumatic origin. Prognosis doubtful. The disease assumed a favorable course under appropriate treatment. Complete recovery occurred at the end of about five weeks. When the symptoms of cerebral irritation subsided, on the fifteenth day, the knee jerks returned and were well marked. Their loss was probably due to the cerebral irritation exciting excessive inhibition.

In the fatal case of a child with lobar pneumonia, complicated by meningitis, the knee-jerks disappeared before the symptoms of meningitis were manifested. They were absent over a week and became well marked, even exaggerated, when pressure symptoms were evident a day or two before death.

It is of interest to note that Hughlings Jackson has recently shown that the knee-jerk is lost when there is a supervenescence of the blood, in asphyxia from coal gas, in the acute stage of some cases of apoplexy, etc.

In distinguishing a genuine epileptic convulsion from simulation, we must consider the absence of the knee-jerks and the absence of the light-reflex with dilated pupils as crucial tests in excluding simulation. Of course, it is within the range of possibility that an epileptic fit may be simulated by a person whose knee-jerks are absent as the result of an organic lesion, and in whom dilated and immobile pupils have been artificially produced by atropine. Such an individual would indeed be a rara avis.

The knee-jerk is absent in cases of diabetes only where there is peripheral nerve degeneration. This is manifested by symptoms such as muscular weakness in the extremities, circumscribed anesthesia, and possibly persistent neuralgia, isolated paralyses, and disturbances in the nutrition of the skin, especially perforating ulcers and other gangrenous processes.

We now come to the significance of an exaggerated knee-jerk. It may be considered as exaggerated when slight percussion on the tendon above the patella elicits an active response. In brief, it may be said that any obstructive or destructive process involving the upper or cerebrospinal segment of the motor tract is likely to and generally does occasion an exaggeration of the knee-jerk. Should the lesion be situated above the crossing of the motor tract, the exaggeration occurs upon the opposite side of the body, while a lesion below this point would manifest its symptoms on the same side.

The prevailing and accepted view to-day is that the reflex centres in the cord receive fibres from the brain which serve to inhibit or control their activity.

In patients who have received large doses of bromide in sufficient quantity to produce some of its physiological effects, as in epileptics, the knee-jerk can always be found either well marked or exaggerated. During the last ten years I have been in the habit of demonstrating this peculiarity in all cases of epilepsy appearing at the clinic. This phenomenon is due to the sedative action of the bromide on the motor cortex, thus diminishing the cerebral control over the lower reflex centres.

Primary or secondary degeneration affecting the lateral columns of the cord (spinal portion of the upper segment of the motor tract) is usually attended by exaggeration of the knee-jerk upon the same side as the lesion. In some cases of hemiplegia resulting from hemorrhage in the internal capsule I have found the knee-jerk exaggerated (and ankle-clonus) on the third or fourth day. This is too soon for the development of a secondary descending degeneration, but is more likely due to a cutting off of the inhibitory fibres. In the early stage of parietic dementia, owing to the pathological changes in the cortex, the knee-jerk is often found markedly exaggerated, save in those cases where the posterior columns of the cord have been primarily involved. Then the knee-jerk may be lost. As the knee-jerks are often found pronounced or excessive in neurasthenia, hysteria, and alcoholism, or from mental fatigue, we must admit that in many instances the interpretation of such a symptom is more difficult than when the knee-jerks are absent. This is particularly the case when the overactivity is bilateral and uniform in character. A unilateral exaggeration of the knee-jerk is often of considerable pathological significance, and is usually associated with other objective symptoms, such as diminished muscular resistance, paresis, or rigidity.

From these cursory remarks it will be seen that in the study of the knee-jerk, as in other conditions, "correct observation is a matter of the greatest necessity, for on what we observe we have to make an interpretation and frame a line of action; consequently, if the observations are faulty, the interpretations we place upon them are valueless."

The Ohio State Medical Society.—The present officers of the society are as follows: President, Dr. Dan Millikin, of Hamilton; vice-presidents, Dr. J. H. Goss, of Lancaster, Dr. W. H. Hamiston, of Cleveland, Dr. J. A. Murphy, of Cincinnati, and Dr. B. M. Ricketts, of Cincinnati; secretary, Dr. Thomas Hubbard, of Toledo; assistant secretary, Dr. H. W. Moore, of Columbus; treasurer, Dr. James A. Duncan, of Toledo.
OBSERVATIONS ON
EXCESSIVE INTESTINAL PUTREFACTION.*

By C. A. HERTER, M.D.,
VISITING PHYSICIAN TO THE CITY (CHARITY) HOSPITAL;
CONSULTING PHYSICIAN TO THE BABIES' HOSPITAL;
PROFESSOR OF THE ANATOMY AND PATHOLOGY OF THE NERVOUS SYSTEM,
NEW YORK POLYTECHNIC,
AND E. E. SMITH, Ph. D.

(Continued from page 784.)

Little is known at present as to the occurrence of pheno-

tol-potassium sulphate, except that it is present in health

as one of the regular constituents of the total ethereal sul-

phates. It has been found by various observers that it is

increased in some conditions of disease. Thus Salkowski

found it in inanes and peritonitis, and Brierer in anae-

mia and cachexias, and von Jaksch* states that Stra-

sen has found it regularly present in increased amounts in

diabetes, although no change in the sulphate ratio was

observed. The methods used for determining phenol included

also the cresol present. It was formerly held that the

amount normally present did not exceed 0.03 grammes in

the urine for twenty-four hours, but more recent methods†

give much higher results—0.07 gramme and 0.105 grammes.

We do not know what are the conditions that deter-

mine a pathological increase of phenol rather than indol,

and as yet a knowledge of the amount in which it is pre-

sent has been made of little practical value. Likewise,

practically nothing is known regarding the special signi-

ficance of the presence of skatol, cresol, and catechol.

We have elsewhere mentioned the occurrence of quinol

and catechol in the urine of some cases of epilepsy.‡

We may now pass to the consideration of some of the

clinical conditions in which excessive intestinal putrefaction

is met with sufficient frequency to put it beyond the range

of an accidental association.

Excessive Intestinal Putrefaction in Intestinal Indiges-

tion.—In recent years there has been a disposition on the

part of clinicians to recognize the existence of cases of

indigestion in which the symptoms point with reason to in-

testinal rather than gastric disturbance. In some instances

text-books of practical medicine have taken note of this

distinction, but their treatment of the subject must be re-

garded as inadequate and often misleading. The reason

for this shortcoming is to be found in the inherent difficul-
ties of the subject.* The symptoms to which intestinal

indigestion gives rise vary a good deal in different cases,

and are often mingled with the symptoms of unquestioned

gastric indigestion. In such instances it may be impossible

to say with certainty what shall be referred to the in-

testinal disorder. In other cases the symptoms and signs

which would usually direct attention to the intestine are so

slight as to be readily overlooked, although the constitu-
tional effects resulting from the derangement may be pro-

ounced. But in many cases where the symptoms, whether

pronounced or equivocal, are those which suggest intesti-
nal rather than gastric disturbance, there are present the

objective evidences of excessive intestinal putrefaction.

Whether or not signs and symptoms referable to the in-
testine exist in every case where excessive intestinal putrefac-
tion is present could be decided only by the most extended

and painstaking clinical study. Cases perhaps occur in

which such excessive putrefaction gives rise to slight or no

intestinal symptoms. But however this may be in excep-
tional instances, we have met with no case where such

excess has been considerable in degree in which there have

not been also present signs and symptoms which might

fairly be interpreted as those of intestinal indigestion.

Moreover, in numerous cases the study of the patient has

been sufficiently close to establish beyond question a rela-
tionship, in individuals, between the occurrence of the evi-
dences of this excessive putrefaction, on the one hand, and,

a group of varied symptoms, including local and general

manifestation, upon the other.

The following histories are presented here in order to

illustrate some of the clinical manifestations occurring in

cases in which it is reasonable to consider intestinal indi-
gestion a prominent factor, and in which the objective

evidences of excessive intestinal putrefaction were posi-
tively ascertained.

These cases are instructive, as showing the coincidence of
certain signs and symptoms with the excess of aromatic

sulphates in the urine. The cases which have been chosen

for presentation illustrate to some extent the variety that

exists in the manifestation of intestinal indigestion. We

are not yet in a position to describe with entire satisfaction

the symptomatology of intestinal indigestion, but will at-
tempt a discussion of its leading features after the clinical

histories have been recorded and commented upon:

Case I.—I., Jl, female, aged thirty years; weight, one hun-
dred and twenty pounds; married. Has always been well, bar-
ring occasional periods characterized by abdominal pain, disten-
tion, intestinal flatulence, and constipation, associated with loss
of appetite and general malaise, the entire disturbance lasting
one or two days. Patient came under observation May 3, 1892.
Just previous to this was in good general condition, with good
appetite and no apparent disturbance of digestion; there was slight constipation; stools were large, light brown in color, and natural in odor. Mixed diet, with moderate use of sweets, pastries, etc. About November 5th patient was troubled with obstinate constipation, intestinal flatulence, occa-

sional slight abdominal pain, and a sense of fullness in the ab-
domem after meals. A small movement was very offensive in

odor and contained considerable mucus. Appetite good, no

headache, sleep uninterrupted with dreams and intervals of wake-

fulness. An examination of the urine collected during November

5th (twenty-four hours) gave among other results of analy-

sis the following:

<table>

* Loc. cit.
‡ Herter and Smith. Loc. cit.
* The readiness with which the gastric contents can be studied ac-

counts for the large literature upon disorders of gastric digestion.

The very small extent of the literature of intestinal disturbances of di-

gestion plainly reflects the difficulty of investigating this class of dis-

orders.
The significant features of this analysis are the high combined sulphates and the great excess of indigo blue, together with the presence of a normal uro-Neill ratio.

The patient's condition improved somewhat after the exacerbation above recorded; the abdominal pain, flatulence, and constipation were away and sleep became normal. There is no record of the putrefactive products in the urine at this time. On December 7th the patient again felt poorly and had some intestinal flatulence and was without appetite. Analysis of urine for the day:

<table>

</tr>
</tbody>
</table>

At this time a restricted diet was instituted, consisting chiefly of meat, milk, eggs, with limited vegetable nitrogenous food. Five grains of sodium salicylate were given after each meal. From this time on, doubtless in consequence of the restriction in diet, the ratio of the sulphates fell and remained for some time within the normal. There was, however, little actual improvement, the patient continuing to be troubled more or less with flatulence, slight headache, and general debility. It is noticeable that during this period indigo blue was obtained from the urine in large amount. The figures for this period are as follows:

<table>
<thead>
<tr>

<td>2082</td>
<td>0180</td>
<td>10:6</td>
<td>Strong</td>
<td>20615</td>
</tr>
</tbody>
</table>

On February 12th the patient's condition was worse than it had been since November 6, 1892. There was a return of the symptoms present at that time: slight abdominal pain and distention, flatulence, loss of appetite, depression of spirits, and debility. The analysis for this day gave the following results:

<table>
<thead>
<tr>
<th>Substance</th>
<th>Grams</th>
</tr>
</thead>
<tbody>
<tr>
<td>Preformed sulphate</td>
<td>1410</td>
</tr>
<tr>
<td>Combined sulphate</td>
<td>0181</td>
</tr>
<tr>
<td>Ratio</td>
<td>7:5</td>
</tr>
<tr>
<td>Indigo blue</td>
<td>Medium strong</td>
</tr>
</tbody>
</table>

The area for this day was rather lower than on previous days, as might be expected, the total being 19, as against 16, 23, 18, 25, 43, 22, and 29 for previous days. The above results are interesting, chiefly because of the contrast in this ratio of sulphates with the ratio of previous days (the ratio 7:5 being the first above the average normal 10 observed since December 7, 1892), and because of the coincidence of this high ratio with a distinct exacerbation of the symptoms.

On February 23d the patient's condition was distinctly better than usual and the analysis for this day showed a marked contrast with that of the day on which it was last recorded.

The figures are as follows:

<table>
<thead>
<tr>
<th>Substance</th>
<th>Grams</th>
</tr>
</thead>
<tbody>
<tr>
<td>Preformed sulphate</td>
<td>2119</td>
</tr>
<tr>
<td>Combined sulphate</td>
<td>0158</td>
</tr>
<tr>
<td>Ratio</td>
<td>13:4</td>
</tr>
<tr>
<td>Indigo blue</td>
<td>Traces only,</td>
</tr>
<tr>
<td>Urea, grammes</td>
<td>25:9+</td>
</tr>
</tbody>
</table>

It should be noticed that for the first time since this case was under observation the indigo blue amounted to traces only. The next day, February 24th, the condition is described as average. There were still only traces of indigo blue, but the ratio of sulphates was higher (11:3) than it should be on a restricted diet.

On April 6th and on May 9th, the condition being on these days respectively fair and better than usual, the following figures were obtained:

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

Case II.—R. M., aged forty-three years; weight, a hundred and forty-five pounds. Mother died of carcinoma of mamma. Brother died of diabetes. Delicate health early in life; pulmonary haemorrhages at twenty. Gradual improvement in health since then. During past year has been neurasthenic, being troubled especially with sleeplessness, frontal headache, undue emotional excitability, and moderate loss of weight and strength. Late in August, 1892, had severe headache and nausea after overexertion and an indiscretion in diet consisting of the free use of buckwheat cakes and trout. The pain in this attack was located on the left side of the head, and was very intense at times and lasted several days. There was much prostration at this time, and the temperature ranged between 100° and 101°. When the acute symptoms wore away it was noticed that the left eyelid drooped considerably, that the left pupil was much contracted, and that the left eyelid was more prominent than usual. Examination showed that sensation on the face was unimpaired, but that the left side of the face was cooler to the touch than the right and paler in color, and that the left side of the face failed to perspire even when perspiration was free on the right side. The fundus was normal, the left supraorbital nerve was extremely tender to pressure, and over the left temple was a small spot of great sensitiveness to the touch.

Before the onset of the present trouble the patient had suffered from time to time with left supraorbital neuralgia. This now recurred with much greater severity and frequency than formerly.

The patient remained in very poor health for many months. The neurasthenic symptoms above mentioned persisted, and there was almost continual discomfort from the accumulation of gas in the intestine, the bowels being often constipated and sometimes loose. The faeces were light in color and often contained a large amount of mucus.

An examination of the urine, made September 26th, showed the presence of excessive intestinal putrefaction. During the five months following, most of the examinations made showed some excess of the putrefactive products, especially an excess of indican. The quantity of indican was certainly greatest at times when the patient was most depressed and was suffering from intestinal flatulence and constipation. After the first, the ratio of the sulphates, as shown in the appended table, returned to within the limits of the normal, but this was unquestionably owing to the exclusion from the diet of the vegetable nitrogenous foods.

With the gradual improvement which set in, the urine returned to normal as regarded the amount of putrefactive products contained in it, and indigo blue was no longer found.
The results obtained in this case are as follows:

<table>
<thead>

On December 4th, examination of the urine passed just after an attack of headache, gave:

Preformed sulphate ........................................ 2.465 grammes.
Combined sulphate .......................................... 0.210 grammes.
Ratio ........................................................ 11.7
Urea ..................................................................... 29.879 grammes.

Case III.—C. L. D., female, aged thirty years; weight, about a hundred and twenty-five pounds. Well nourished, slightly anaemic. Has been in poor health for several years. At the present time complains of general debility, lassitude, shortness of breath during exertion, and frequent slight frontal headache. Though not disposed to emotional disturbance, the patient is rather inclined at present to mental depression. Bowels are regular and movements are normal in color and consistence. There is occasional moderate intestinal flatulence. Appetite is fair. There is at times a sense of emptiness and gnawing referred to the upper part of the abdomen. An examination of the urine passed June 4, 1892, gave the following results:

| Urea ........................................................ 19.690 grammes.
| Urine acid .................................................. 0.418 grammes.
| Preformed sulphates ...................................... 1.322 "
| Combined sulphates ....................................... 0.237 "
| Ratio ........................................................ 5.5

The patient was put upon a diet consisting chiefly of meat, and from which sweets, starches, and peas and beans were excluded with especial care. Iron and nux vomica were prescribed and more exercise was advised. In the course of three weeks there was distinct improvement as regards all the symptoms mentioned above, and the improvement noted at this time was maintained for several months. Unfortunately, no examination was made of the urine during the period of improvement, and the record of the case is therefore defective.

Case IV.—C. G., male, aged sixty years; weight, a hundred and seventy-four pounds. Has been in poor health ever since his thirtieth year, when he had what were thought to be pulmonary hemorrhages. Ever since that time he has been neurasthenic, and, at times, has been disposed to be hypochondriacal. The symptoms complained of at present (April, 1892) have existed in greater or less degree than now for many years. These symptoms are debility, insomnia, pressure sensations in the back of the head, headache, depression of spirits, at times very great, loss of memory, "witching sensations" and fibrillation (especially mornings), poor and capricious appetite and constantly coated tongue, intestinal flatulence with great distention of the abdomen, abdominal pain, alternating diarrhoea and constipation, occasional cardiac palpitation and tachycardia, and frequent passage of gravel in considerable quantities. The progress of the patient’s troubles is by no means even; there are days of comparative well-being, followed by days of depression and exacerbation of all the symptoms. It is a noticeable fact that periods of mental depression and debility, insomnia, and impaired memory correspond to the time at which the intestinal symptoms, flatulence, abdominal distention, etc., are most pronounced.

Examination of the urine were made from time to time. The results are recorded below. About the time of the first examination the patient was placed under treatment consisting chiefly of the careful regulation of the diet (which up to this time had been free) and the use of tonics. Vegetable nitrogenous food was excluded so far as possible from the diet. Rest was also insisted upon. Some improvement occurred immediately and in the course of a year the improvement was considerable. This improvement consisted in an increase in the periods of well-being and a decrease in the periods of depression and intestinal disturbance, so that the average condition was better notwithstanding the recurrence of most of the symptoms.

Case V.—A. L., male, aged sixty years; weight, two hundred and twenty-seven pounds. General health has always been excellent. Is a hard worker and an abstemious man in every respect. Takes claret with meals and whisky in moderation. For three years past has been troubled each spring with a general urticaria which lasted many weeks. Thinks he is run down at these times. Has a "tendency" to rheumatism; is apt to be troubled with painful and rigid muscles, especially those of the neck. Has found of late that he tires very readily and that sleep does not refresh him as formerly; he gets up tired. Has also been troubled with mental dullness, defective memory, and irritability. The abdomen is most of the time considerably distended by gas, a great deal being passed per rectum. At times there is abdominal pain. There is frequent epigastric discomfort and sometimes tenderness on pressure below the sternum. Some days there is almost constant slight nausea. The stools are usually clay-colored. Examination of the urine gave the following results:

On a diet from which sugar and starch and vegetable nitrogenous food was largely excluded the symptoms above enumerated disappeared very rapidly. At the end of six weeks there was improvement in the following respects: Sleep was more refreshing, the head felt clearer, memory was better, and fatigue came on less readily. There was also entire disappearance of nausea and a great diminution in the abdominal distention and flatulence. The rheumatic pains in the neck ceased after a few days and have not recurred.

An examination of the urine made at this time gave the following results:

Shortly after this the patient indulged in a large dinner, without any restraint, using champagne freely and taking lobster soup, sweets, etc. The day following he felt dull mentally, and, for the first time in many weeks, there was a return of nausea. There was also considerable intestinal flatulence. Then, returning to a strict diet, improvement again set in. The urine of June 14th and 15th was studied, the patient being in better condition than usual. The results are:

CASE VI.—J. L., female, aged twenty years; weight, about a hundred and forty pounds. General health good, but has suffered ever since her twelfth year from indigestion. At the present time suffers from pain in the epigastrium soon after eating, and very frequently there is abdominal pain associated with great intestinal flatulence and distention of the abdomen by gas. There is very rarely gastric flatulence. While these abdominal symptoms are present the patient feels weak and somewhat depressed. The sensation of emptiness and exhaustion is relieved temporarily by food. Frequently there is nausea all day long, very rarely there is vomiting. Bowels are regular and faces are normal in appearance. The patient is a large eater and takes whatever appeals to her appetite without much reference to her condition.

Examinations gave the following results:

CASE VII.—H. A. C., male, aged twenty-eight years; weight, a hundred and fifty pounds. Has always been in good health, barring an occasional severe migraine. In October, 1892, had an attack lasting nearly a week, during which there was almost continual abdominal pain, flatulence, diarrhoea, moderate fever and prostration. The stools were not watery, but consisted of large, almost white, cheesy movements without the characteris-

tic fœcal odor, and resembling the peculiar stools not rarely seen in children with intestinal disturbance. This attack was brought on by eating oysters that were partly decomposed. Ever since this attack there has been a tendency to the occurrence of slight intestinal disturbance, especially after the use of lobster and oysters and clams, even when apparently fresh, and after the use of peas and beans. These periods of intestinal disturbance last a day or less, and are sometimes associated with or followed by diarrhoea. They have these symptoms in common: slight or considerable abdominal pain, intestinal flatulence and borborygmæ, general malaise, and usually slight mental depression. The urine in this case ordinarily contained no indican, but during the periods above mentioned was regularly found to give a medium strong reaction. The correspondence in this case between the presence of indican and this group of symptoms was strikingly close. For example, on April 30, 1893, an indiscretion in diet was followed in a few hours later by slight abdominal pain, flatulence, borborygmæ, frequent micturition, and depression of spirits. The urine passed (two micturitions) during the remainder of the day gave a medium strong indican reaction. The following day the symptoms had ceased, and no more indican was found during the following week although the urine was tested several times each day. On May 9th the eating of lobster in the middle of the day was followed in a few hours by abdominal pain, flatulence, and borborygmæ. The first urine passed after the beginning of this attack contained indican. After about three hours the symptoms ceased almost as abruptly as they had begun; the urine passed next gave no indicine-blue reaction. The following morning there was a recurrence of the above symptoms without the diarrhoea, lasting several hours, and the urine passed in two successive micturitions following the commencement of this attack gave a medium strong indicin-blue reaction. The indican disappeared from the urine with the disappearance of the symptoms.

The record of this case is defective in that the sulphates were not determined throughout. At times, however, the ratio of the sulphates has been normal when indican was present and intestinal flatulence was complained of.

CASE VIII.—H. P., male, aged twenty-two; weight, a hundred and forty pounds. Has been in fair health, barring susceptibility to colds in the head and attacks of laryngitis, and frequent acute disorders of digestion. On February 7, 1893, patient ate a good many fried oysters for breakfast. Next day he suffered from intestinal pain, borborygmæ, flatulence, nausea, and malaise. The pain soon disappeared, but there was more or less intestinal disturbance for many days. Examination made February 10th and 11th showed very strong indican reactions. As the patient improved gradually the indican and etherial sulphates decreased in amount, but remained for a considerable time in excess of the normal.

CASE IX.—C. H., girl, aged two years and a half; weight, thirty-two pounds. Has always been in good health and remarkably free from digestive disorders. About January 25, 1893, without known cause, began to be restless and irritable. There was much loss of appetite, slight constipation, and slight fever. The stools were rather lighter than normal in color; otherwise there was no indication of digestive disorder. These symptoms continued with little change till about February 10th. The slight elevation of temperature was almost continual, fever ranging between 99° and 100°. During this time there was loss in weight (about a pound and a half). There was no evidence during this period of the existence of abdominal pain, or flatulence, or headache.
The urine had been examined repeatedly previous to the period of illness recorded above. At no time was any trace of indigo blue found, and the sulphates were in each instance normal. The results given below represent the conditions found before, during, and after the illness:

Several attacks similar to that recorded have occurred since, and in every instance indigo blue has been present at the time of the fever and digestive derangement, and for some days afterward in diminishing amounts. It is noticeable that the period during which indigo blue persisted in the urine after the subsidence of the acute symptoms of the attack has been increasing. At present (March, 1893) there is probably a trifle of indigo blue in the urine most of the time. The following results have since been obtained:

Case X.—A. K., aged fifteen months. On admission to the Baby's Hospital in December, 1892, weight seventeen pounds eleven ounces; tolerably nourished; milk diet. Soon after admission the symptoms were as follows: Vomiting, poor appetite, light-green or white stools, feeble pulse, somnolence, prostration, and slight irregular elevation in temperature (under 100°). On December 24th, a little more than a week after admission, the stools were fluid, green, offensive in color, and contained mucus, small greenish masses, and something having the appearance of membrane. The child was in a stuporous state at this time, and it was noticed that there was considerable rigidity of the lower extremities. This rigidity was intermittent, and excited by movement or stimulation of the skin.

The intestinal symptoms continued without important changes. Early in February, 1893, there was a considerable increase in the rigidity, which now involved the arms, legs, and trunk, and became continuous. There was great exaggeration of the knee-jerks and typical and violent ankle-clonus. The child cried as it in pain when touched. No evidence of organic brain or spinal-cord disease. There was a sharp rise in temperature about this time. Loss of weight between admission and February 1, 1893, nearly four pounds. By March the general condition had improved considerably; increase in weight; appetite better; stools less often green, frequently normal; temperature normal; less rigidity; and less evidence of pain to touch.

During March the weight increased rapidly, rigidity became slight, and frequently no clonus could be obtained. By May 1st rigidity occurred only at times, and, though the knee-jerks were active, ankle-clonus could rarely be brought out, and then only feebly. At no time was there paralysis in the lower extremities or loss of sensibility. The electrical reactions were not taken.

During the period of spasm and pronounced intestinal disturbance the urine contained very large amounts of indigo and high ethereal sulphates. As improvement occurred, these evidences of excessive intestinal putrefaction grew less and finally disappeared entirely.

The results obtained in this case are as follows:

At one time the symptoms in this case strongly suggested pressure on some part (cervical) of the spinal cord. It is now a question whether the case may be regarded as one of tetany, notwithstanding the absence of the characteristic contractions.

Case XI.—L. R., aged fifty years; weight, two hundred and twenty-two pounds; well-nourished man. For about a year he had had occasional periods of nocturnal dyspnea. These have recently become frequent and very distressing, accompanied with cyanosis, precordial fear, etc. Examination shows presence of nitral regurgitation and moderate hypertrophy. Symptoms at present are those of broken compensation, dyspnea, cough, intermittent pulse, slight icterina of feet, and scanty urine. The onset of dyspnea seems to be occasioned at times by great accumulation of gas in the intestine. For a year past intestinal flatulence, with borborygm and distention of the abdomen, has been an annoying and almost constant symptom. No diarrhoea or constipation. No depression of spirits, but a good deal of irritability, frequent headache, and considerable loss of physical endurance. Examination of the urine showed a medium strong indigo-blue reaction, normal sulphates, very exces-sive uric acid, and considerable oxalate of calcium.
of the local symptoms of intestinal indigestion, the most characteristic and the most important for diagnostic purposes is unquestionably intestinal flatulence. By intestinal flatulence is meant the accumulation of gas in the small or large intestine. This gas is usually passed per anum, but may be in part eructated by the stomach. It is necessary, of course, to distinguish intestinal from gastric flatulence, and to bear in mind that gas formed in consequence of gastric indigestion solely may be passed on to the intestine. The degree of flatulence varies greatly. In many cases there are no pronounced evidences of the presence of gas except the frequent passage of wind by the anus; there is no appreciable abdominal distention. In other cases there is marked abdominal distention, and not rarely slight pain, or at least a sense of discomfort, in the abdomen due to excessive peristalsis. The distention of the abdomen with gas may be a most distressing symptom. In Case IV frequent great abdominal distention was, perhaps, the most annoying symptom, and its presence seemed in several instances to occasion the onset of attacks of tachycardia lasting several hours and disappearing with the relief of the distention. In Case XI also great abdominal distention was of frequent occurrence, and at times appeared to determine the onset of the nocturnal dyspnoea due to the nitral insufficiency.

The association of intestinal flatulence with abdominal pain and with excessive peristalsis (symptoms often following palpable errors of diet) at one time made it appear probable that this symptom was to be considered an evidence of disordered intestinal digestion. But observations made upon the urine of persons having intestinal flatulence failed to furnish good evidence that such flatulence is usually associated with excessive putrefactive processes in the intestine. In some cases, however, where a sufficiently careful record has been kept to enable a judgment to be formed, there has been a close correspondence between the existence of flatulence and the presence of indican in the urine. This was so in Cases I, II, IV, and VII, and in some cases not included in the preceding histories. In Case VII, in which there were frequently repeated slight attacks of intestinal indigestion, the urine was examined several times daily for many weeks, and the correspondence between the occurrence of flatulence and the appearance of indican in the urine was strikingly close. In every instance the urine passed after the beginning of flatulence gave a medium or weak indican reaction which disappeared as soon as the symptoms wore away. In no instance did the urine passed in the intervals between the intestinal disturbance contain any indican. In Case I the diminution of indican coincided with marked diminution in the flatulence and other intestinal symptoms. In Case II the indican was greatest in amount at the time when intestinal flatulence was an annoying symptom. Since the disappearance of indican from the urine there has been entire relief from flatulence, although certain other intestinal symptoms, as light colored and mucous stools and constipation, have
In the second class of cases it is probable that the food is not at fault primarily, since the modification of the diet has relatively little effect upon the indican. From the constancy of the indican it seems probable that there is present a persistent condition of the intestine concerned with the production of indol. We have already noted the fact that indican is formed from the mucus of the bile, and it occurs to one that in these cases the putrefaction may depend on the presence and stagnation of an excessive amount of intestinal mucus from the bile or other source.

The persistence of this condition indeed leads to a suspicion that somewhere in the duodenum the mucus membrane is in a state of catarrhal inflammation to which the excessive formation of mucus might reasonably be referred. The absence of flatulence at times in these cases would be explained by the fact that the food does not necessarily share in the putrefactive process. We have, of course, no proof that this view of the case is the correct one, but it seems to harmonize with what is known about the causes of intestinal putrefaction. It is interesting to note in this connection certain of the facts relating to the occurrence of intestinal putrefaction in starvation. These facts are, the occurrence of large quantities of indican in men and animals in starvation, the absence, so far as known, of flatulence, and the accumulation in the intestine, in this state, of a peculiar kind of feaces, consisting largely of broken-down epithelial elements, mucus, etc.

Abnormalities in the feaces, as shown by changes in their appearance or in their chemical characters, are of frequent occurrence in the subjects of intestinal indigestion, and were noted in many of the cases recorded above. As might be supposed, no relation has been established between the occurrence of such abnormalities and excessive intestinal putrefaction, and it would take far more careful studies than any which have yet been made to determine whether or not such a relation exists. A number of things seem to indicate that many of the peculiarities in the feaces seen in cases where excessive intestinal putrefaction occurs are to be considered evidence of intestinal indigestion.

Thus the presence of clay-colored stools is a feature of many cases where the sulphates are excessive and indican is abundant, and there is some reason to ascribe this condition to the defective secretion of pancreatic juice. Again, the presence of fat in excess in the feaces (i.e. much more than twenty per cent. of the solid matter) is frequently met with, and is surely to be regarded as due to defective secretion either of the pancreatic juice or the bile or both. Another point which it might pay to study is the ratio of the fatty acids in the feaces to the neutral fats, since a marked disturbance of the normal ratio (say from eighty to forty per cent.) is regarded by some authors as positive evidence that the pancreatic juice is not nitrogeous food of the kind readily digested, and which is thus least apt to undergo putrefactive changes, is followed by the disappearance of the flatulence and indigo blue.
doing its part in intestinal digestion. It would also be of interest to note carefully the quantity of sterobilin in the feces, this being very abundant in some persons having an excess of the putrefactive substances in the urine. This is, however, also found in excess in persons in whom no excess of intestinal putrefaction is present. A very hurried passage of partially digested or almost unchanged food along the alimentary canal is apt to occur from time to time in those who are the constant subjects of excessive intestinal putrefaction, but it is doubtful if this is any evidence of defective or altered intestinal secretion. It is rather evidence of defective absorption and excessive peristalsis. But it is probably fair to regard its occurrence as one of the signs of intestinal or gastro-intestinal indigestion. There is reason to believe that during such active peristalsis aromatic putrefactive products are absorbed from the intestine in only very small amount.* The occurrence of considerable mucus in the stools is a common occurrence in intestinal indigestion, and doubtless often depends on an enteritis. It does not appear to bear any close relation to the occurrence of intestinal putrefaction.

The influence of constipation on the appearance of putrefactive substances in the urine has been discussed elsewhere. It is important to note here the frequent occurrence of constipation in those who have the symptoms of intestinal indigestion. It is, however, certain that constipation, using the term in its ordinary sense, can not be solely responsible for the increase of putrefactive products found in the urine in intestinal indigestion. This is shown by the fact that in some cases these products continue present in excess, and with little or no diminution after the constipation has been relieved. But it should be remembered that there may be in some of these cases an abnormal delay in the passage of feces through the intestine although there is a daily movement. Such a condition, if it occurs, would constitute a virtual if not an apparent constipation, and might be responsible, in a measure at least and in some cases, for the appearance of high ethereal sulphates. In order to be able to judge regarding this point, we ought to have more information about the rapidity with which food normally makes its way through the intestine.†

A minority of the subjects of intestinal indigestion complain at times of some form of abdominal pain. Sometimes the pain is spasmodic and migratory, being referred first to one part of the abdomen, then to another—usually

 fatty acids. Here there was probably an excessive fat-splitting action on the part of the fermentative bacteria, due probably in this case to the redness in bile. See Bielert.

† Some patients have been able to judge of the rapidity of this progress by the appearance in the feces of spinach taken with the food. It is probable that food normally passes through in somewhat less than twenty-four hours.

to the lower part of the abdomen, and frequently to one or other side. This colic is commonly associated with flatulence, and perhaps with some degree of abdominal distention. There is, of course, no doubt as to the dependence of this pain upon spasm of the muscular coats of the intestine. It is due, probably, in most instances to the irritation produced in the course of putrefactive changes in food during intestinal, probably pancreatic, digestion. The pain may, it is said, have nothing whatever to do with intestinal indigestion and be of centric origin, so that we can not always regard it as indicating intestinal indigestion. The epigastric pain which comes on in some of the patients who have excessive intestinal putrefaction is more difficult to interpret. The pain varies much in intensity in the same and in different persons, and in the time of its onset after a meal. It may be difficult to decide whether, in a given case, such pain is gastric or duodenal. The fact that in some cases it is relieved by washing out the stomach seems to show that it may be of gastric origin. According to Golding Bird, undue relaxation of the pylorus, with a rapid escape of the stomach contents into the duodenum, is the explanation of the pain in the intestinal cases, but it is doubtful whether this is really the explanation. The length of time at which the pain comes on after eating does not, as pointed out by Alchim,* aid in the determination of the origin of the pain, for gastric and duodenal digestion progress to a considerably extent simultaneously.

In some cases where there is excessive intestinal putrefaction there is not only severe and continuous epigastric pain, but also great tenderness on pressure over a limited area an inch or two below the sternum, suggesting organic stomach disease. We do not know how and where this pain and tenderness are caused, and it is not our intention to inquire here into its nature. The same symptoms occur, however, in some persons with enormously excessive uric-acid excretion without excessive intestinal putrefaction, and in other cases, where such putrefaction exists, have cleared up under treatment which did not affect the putrefactive products in the urine. We may conclude, therefore, that these symptoms—epigastric pain and tenderness—probably are in no wise dependent on intestinal putrefaction, even though they may be of intestinal origin in some cases.

Another symptom of frequent occurrence in cases where intestinal putrefaction is excessive and referred to the epigastrium is a feeling of emptiness, described by some patients as a "gone feeling." In some patients this is a very prominent and distressing symptom. The feeling is usually intermittent, and is apt to be particularly pronounced when the patient is tired, especially late in the afternoon. An empty stomach is a condition favorable to its development, and the taking of food usually relieves the sensation, at least for a time. That an empty stomach is in some cases not essential to its production is shown by the fact that a considerable quantity of food may give relief for only a few minutes. According to Golding Bird this symptom also may be due to the too rapid passage of food into the duodenum, for this feeling of faintness, together with

* On Duodenal Indigestion. Lancet, 1890.
flushing of the face, rapid pulse, etc., made its appearance in a case of jejunoestomy when from fifteen to twenty ounces of food were introduced directly into the intestine, but did not appear when the quantity mentioned was much reduced. But, whatever may be the origin of this sensation, whether it be gastric or duodenal, it is certainly not directly related to excessive intestinal putrefaction. This is shown by the fact that it often occurs in cases where putrefaction is not excessive, and that in other cases it is relieved without any corresponding lessening of the putrefactive products in the urine. In these respects the symptom resembles epigastric pain, with which it is not rarely associated. It is related to epigastric pain in still another way—namely, in its frequent occurrence in persons who are excreting an excessive amount of uric acid, and in the relief of both symptoms when the diet is so altered as to diminish the uric-acid output materially. These facts lead one to suspect that both epigastric pain and the sensation of ghneness may be due at times, and in part at least, to imperfect or perverted digestion in the small intestine, notwithstanding the absence of any relation to excessive putrefaction in the intestine. In other words, we must be prepared to recognize the existence of intestinal indigestion without excessive intestinal putrefaction. We do not wish to be understood to mean that epigastric pain and faintness and uric-acid excess are conditions necessarily dependent on intestinal digestion. It is highly probable that all these conditions may depend sometimes on disturbance limited to or at least initiated in the stomach. Stomach indigestion is associated more often than not with intestinal indigestion, and the defective preparation of the food in the stomach for intestinal digestion, through defective secretion, for example, of hydrochloric acid, is thought to be a cause of intestinal indigestion and of excessive putrefaction.

In this connection it is to be also remembered that gastric hydrochloric acid normally exercises a retarding influence on bacterial activity in the small intestine, and that hence a diminished secretion of this constituent of the gastric juice constitutes a condition favorable to putrefactive processes.

The digestive process is, however, more largely carried on in the intestine than in the stomach, and there is reason to think that in most cases where excessive uric-acid output depends on digestive derangement it is due chiefly to intestinal indigestion.

The only remaining local symptom of intestinal indigestion is nausea. Nausea, like vomiting, is certainly more often a gastrie than an intestinal symptom. But cases are occasionally met with in which nausea, lasting perhaps several hours daily, is accompanied by symptoms, such as flatulence and clay-colored stools and abdominal pain, which prove the existence of intestinal indigestion, and unaccompanied by any symptoms that point to gastric indigestion (acidity, heartburn, pyrosis, gastric flatulence). This nausea, which under these circumstances may be a most distressing condition, is quickly relieved by a diet (such as an exclusive meat diet) which relieves the other evidences of intestinal indigestion. Nausea of intestinal origin probably stands in no direct relation to the element of excessive intestinal putrefaction, though it frequently is associated with such excess.

The remote symptoms of intestinal indigestion are exceedingly numerous, and occur in combinations so varied as to baffle adequate description. Some of the following symptoms are usually associated with the local symptoms of intestinal indigestion that have just been referred to: Malaise, habitual or occasional; lassitude; aversion to exercise, which rapidly fatigues; involuntary muscular twitchings (occasionally observed), especially of the muscles of the back; flushing of the face, particularly after fatigue or after food; cold and moist extremities; irregular and habitual rapid heart action, perhaps attacks of tachycardia; drowsiness during the day; insomnia at night; hypochondriacal periods, or periods of slight mental depression; impaired appetite; loss of weight; periods during which there is very frequent micturition. Most of these symptoms, when continued, are the symptoms of neurasthenia, and there can be no doubt that chronic intestinal indigestion is one of the most frequent and effective causes of the neurasthenic condition. When we come to inquire into the relation of the remote symptoms enumerated above to the state of excessive intestinal putrefaction so often the important factor in intestinal indigestion, we find the task a difficult one, for we find the facts to be as follows: 1. Many of the remote symptoms enumerated occur in persons in whom there is no indication whatever of intestinal putrefaction in excess, but in whom too much uric acid is being excreted, and who have some of the local signs of intestinal indigestion. 2. There are cases of intestinal indigestion in which the products of intestinal putrefaction are in excess, but in which the remote symptoms enumerated are not pronounced. These facts, in the form just stated, might lead us to think the occurrence of excessive putrefaction, with its remote symptoms, to be accidental and not expressive of any causal relationship. When, however, the following considerations are borne in mind, we see that there is no ground for entertaining this view, for (1) the remote symptoms which occur where there is intestinal indigestion without excess in the putrefactive products are slighter in degree than when such excess becomes associated with it, and (2) remote symptoms are seldom or never entirely absent when excessive putrefaction is present, and are usually very pronounced when such excess is large. But, while we must recognize the fact that the products of excessive intestinal putrefaction are related in some way to the occurrence of the remote evidences of intestinal indigestion, it must be owned that we can not distinguish clearly between the symptoms that occur in this association and those that arise where the intestinal indigestion is unassociated with such excess, but with too large a uric-acid output. It may be that a difference exists in the nature of the symptoms in the two sets of cases—indeed, it is likely—but much more extended study is required to bring it out.

It has seemed as though mental depression was especially likely to occur when the ratio of the sulphates is very low (lower than one to five), and it is possible that this is so; but the same symptom has been noted with very high uric acid and no abnormality in the sulphates, and occasion-
ally the sulphates run very high without appreciable mental depression.

We are likewise in the dark as to the manner in which the remote symptoms arise in cases where the putrefactive products are present in excess, and in the present state of our knowledge a discussion of the possibilities is futile. It may, however, be pointed out here that there does not seem to be much likelihood that the ethereal sulphates are in themselves responsible to a considerable degree for the remote symptoms. It is more probable that these symptoms depend largely upon the absorption from the intestine of toxic substances formed there coincidently with and in consequence of the putrefaction of, whose extent the ethereal sulphates are the index. At the same time we are in no position to deny the possibility that the various aromatic substances excreted as sulphates are in themselves capable of exerting some toxic effects upon the organism, and it is not unlikely that under some circumstances this influence may even be considerable.

One variety of the occasionally remote symptoms deserves special notice—the ocular symptoms. In Case 11 there was developed a paralysis of the left sympathetic nerve during a period of acute gastro-intestinal indigestion accompanied with fever and prostration. The development of sympathetic palsy at the time of an acute digestive disorder traceable to an indiscretion in diet may have been mere coincidence. It occurs to one, however, that the transient disturbance in function in the sympathetic may have been due to the absorption from the intestine of toxic substances generated within it. In this instance there is the notable circumstance that the eye affected is upon the side of the recurrent supraorbital neuralgia which has been a feature in the case, and, further, that at the time when the palsy developed there was a sharp attack of supraorbital neuritis upon this side.

The following case of ophthalmoplegia, in which the paralysis came on during an acute gastro-intestinal disturbance occasioned by the use of cheese, is highly suggestive in this connection. Unfortunately, no studies of the urine were made, and we cannot express any opinion as to the existence of excessive intestinal putrefaction at the time of the attack. This case occurred in the practice of Dr. George W. Jacoby, to whom I am indebted for the use of the following history:

M. R., male, aged forty-four years. Well until September 10th. On the evening of that day he and his wife went to a restaurant and ate Swiss cheese and sausage. Remarkable that cheese was not good. He ate more than his wife. During the night his wife complained of nausea and vomiting undigested cheese and sausage; he also complained of nausea, but did not vomit. Following day, nausea, loss of appetite, coated tongue, constipation. Toward evening, fainting, vomiting, slow, weak pulse; almost in a state of collapse; stimulants; castor oil. Violent evil-smelling movements for several days, pains, and great prostration.

September 15th.—Great dizziness and diplopia. Says he has seen double, off and on, for several days. Examination: Almost complete external ophthalmoplegia, both sides, left more than right; the rectus superior seems to be less involved than other muscles. Pupils react normally; nothing else; facial, hypoglossal, special senses, reflexes normal; gradual improvement.

October 1st.—Complete restitution.

In a recent study of the etiology of oculomotorous paralysis, A. Dalichow calls attention to the occurrence of ocular palsy after the use of spoiled meat, especially sausage meat. The extent and distribution of the paralysis appear to vary with the amount of the absorbed poison. When this is slight the paralysis involves especially the intrinsic ocular muscles, and in the severest cases some of the external muscles. In connection with the cases here reported the following notes of the symptoms in a case of sausage poisoning reported by Leber are of interest:

A short time after the ingestion of the sausage meat the patient began to suffer from nausea and vomiting, great thirst, dryness of the throat, and discomfort in the joints. Next day there were stoppage of the salivary secretion and dry and white skin. At the same time ocular symptoms appeared—stoppage of lacrimal secretion, ptosis, double vision, mydriasis, and paralysis of accommodation. These ocular symptoms persisted for some time after the disappearance of the general symptoms.

(The to be continued)

THE POLYMORPHIC EXCRESENCES OR VEGETATIONS OF THE MARGIN OF THE ANUS:
THEIR NATURE, CAUSE, PATHOLOGY, DIAGNOSIS, AND TREATMENT

By WILLIAM BODENHAMER, M. D., LL. D., NEW ROCHELLE, N. Y.

The writer, in selecting this particular subject for discussion on the present occasion, is moved to do so from the fact that these abnormal growths are often of a painful and distressing nature, and their gravity is not generally appreciated as it should be; hence they are frequently neglected, being looked upon as apparently trivial in their nature and consequences, and from the fact, too, that they are often pathognomonic sign or evidence of some serious disease within the rectum, such as ulceration, stricture, hemorrhoidal tumors, syphilis, epithelioma, etc., and also from the fact of their erroneous denomination, classification, and distinction as external hemorrhoidal tumors by some authors.

In the course of his remarks the writer will endeavor to show what the disease called hemorrhoids really and truly is, and also give the etymology, signification, and ap}

---

*Note the large excretion of sulphates from the use of salb, etc., without symptoms.
plication of the words hemorrhoids and piles, all of which, it will be perceived, are important to the exposition and to the just understanding of the subject, and to conclude with a few observations upon the medical or curative treatment of the hemorrhoidal disease.

Description.—The margin of the anal orifice and its immediate vicinity are very liable to a number of abnormal cutaneous growths or excrescences which present many and varied forms, shapes, and figures, and which usually sprout out from the fine and delicate skin about the anus. These vegetations are not, however, absolutely peculiar to the anus alone, for in the female, besides the verge of the anus, these very same kinds of growths are often met with in abundance about the pudendum; and when they are of a venereal character they may be observed upon the glans penis, on the prepuce, or on the labia and vagina. The anal excrescences are sometimes so numerous as greatly to interfere with the normal functions of the parts. The writer once treated a lady whose anal orifice was almost completely filled with these excrescences, which had seriously interfered with defecation. Sometimes, however, they are few in number, and are but seldom single; they are generally small and never attain a large size; their color is a pale red, but they usually are of the color of the skin or muco-cutaneous tissue from which they sprout. They are often of a soft or fragile texture, easily broken and readily made to bleed by violence; sometimes, however, they are quite hard, firm, and elastic, being either smooth, rough, or furrowed on their surface; they consist chiefly of condensed and hypertrophic integument. When in a quiescent state, they seem to possess but little vitality, hence they are endowed generally with but moderate sensibility; they are sometimes attended with painful fissures or ulcerations at their bases, and with a purulent discharge from the same; they but seldom exist alone, but generally coexist with either external or internal hemorrhoidal tumors, or with both. Occasionally, when one or two exist, they are in truth the cuticular remains of what were once external hemorrhoidal tumors, the cavities of which had become obliterated, leaving nothing but firmly condensed flaps of skin. They are occasionally venereal, but by no means always or frequently so, as some authors have declared. The writer, only in private practice, however, has seen but five marked cases of venereal growths at the anus during many years' practice, and they all occurred in females, who doubtless, for obvious reasons, are more exposed than men to this particular growth at the anus.

Fanciful Appellations.—In consequence of the great variety of forms these excrescences present, the Greek, Latin, and Arabic authors many ages ago bestowed upon them different appellations, according to their peculiar shape, appearance, etc., such as condyloma, verrucza, crista, parox, sycoma, thywick, myrmecion, ficus, marisa, etc. These different names, as distinctions of the circumanal cutaneous excrescences, import no useful information as to their real and exact nature, cause, and treatment, and are in this particular instance worse than useless, and only tend to confusion; yet strange, passing strange, some quite recent authors demninate and classify these same cutaneous excrecences as so many external hemorrhoids or piles. Now, such distinctions may be necessary and proper for the dermatologist to diagnosticate a precisely similar cutaneous disease on other and different parts of the body, but he would not, regardless of the locality, be very apt to denominate such as hemorrhoids or piles.

These anal excrescences are minutely described by Hippocrates and Celsus, and both these illustrious ancients recognized the difference between the true hemorrhoidal tumor and them. M. Lieutaud, when speaking of tubercles or excrescences of the anus, was aware of the importance of the distinction between them and true hemorrhoidal tumors. He says: "Ces tubercules qu'on doit bien distinguer des hémorrhôides frêtries occupent les bords de l'anus." (Précis de la médecine pratique, 12mo, Paris, 1776.)

The writer would here observe that with regard to the two Latin terms figus and marisa, they both have reference to the form, shape, or appearance of the hemorrhoidal tumor or excrescence which it sometimes presents. Each of these terms means a fig; the latter, however, means a large, blasted, and unsavory one. The celebrated Latin poet Martial uses the word ficus in the sense here indicated by making a jest upon the dual meaning of it, as presented in the following lines:

"Cum dixi fieus, rides quasi barbarus verba! Et diei ficus, Cecilianae, jubes. Diecimus fieus quas scimus in arboare nasi: Diecimus ficus, Cecilianae, tuos."**

Martial again uses the word ficus in his epigram entitled Epiphium, in which he advises the surgeons not to ride bareback lest it cause hemorrhoids:

"Strangula suecincti venator sume verei; Nam solet a mudo surgere ficus equo."†

The great Latin poet Juvenal employed the word marisa to designate hemorrhoids in the same sense in which Martial used the word ficus to designate the same, as will be observed in the following lines:

... "Sei podice lavi, Caeclutur tumilla, medicus ridiclre, marisse."‡

The two Latin vernacular terms, ficus and marisa, were, however, not generally used by the Roman physicians of that period to designate hemorrhoids, but were subsequently added to the above-mentioned class of fanciful appellations.

Etymology.—These anal excrescences are often caused by diseases within the rectum, and it is of great importance that they should not be overlooked, but strictly attended to; by irritation or inflammation of the fine and delicate skin and muco-cutaneous tissue about the anal orifice; they are also frequently the result of friction, compression, or contusion, or of erosion arising from filth and acidic secretions, or from the venereal virus.

* Epigrammaticum medicé philosopliicum, etc., Lib. i, epig. 66, et lib. viii, epig. 71, 46o, Venelles, 1657.
Origin and Structure.—These singular vegetation originate in the cutis, about the verge of the anus, and are alone the production of the cuticular covering of the part, without involving the cellular tissue beneath it. While the external hemorrhoidal tumor is imbedded or seated in the cellular tissue beneath the skin, which it ultimately involves, the anal excrescence is seated only in the skin itself or in the contiguous mucous-cutaneous tissue. Now, as regards the origin, structure, and formation of the external hemorrhoidal tumors, they are those which appear entirely on the outside of the anus and beyond its margin. They are covered by the common integument, and when small can be distinctly felt to be imbedded beneath the skin in the cellular tissue, and are the result of extravasated blood in the subcutaneous cellular tissue of the part, there deposited, circumscribed, accumulated, and retained, the effusion having been caused by the rupture of a morbid venous or venous capillary, consequent sometimes upon violent straining efforts to expel indurated feces, as well as upon other causes. It is in this manner then that a haematoma is suddenly formed, which is the first stage or commencement of the external hemorrhoidal tumor. Or it may in truth be further said that a tumor thus formed in the subcutaneous cellular tissue is a thrombus, formed not in but immediately on the outside of the blood-vessel which supplied the effused sanguineous fluid to make it. On incising such a tumor and emptying it of the blood clot, which is all it contains, a sac will be seen which is lined with a smooth, soft, and delicate membrane. In making the incision and removing the clot, which is easily done, no hemorrhage or any other bad effect follows, as the writer has demonstrated in numerous instances, and this it seems to him would not have been the case had a veritable blood-vessel been thus treated.

These tumors are sometimes tense and hard, at other times they are soft, and they never bleed. In the first stage, and before regular organization has taken place, they are purely sanguineous, and their color, as seen shining through their thin and transparent envelope, is bluish, deep red, or opaque. When the same kind of tumors are serious their color is pale and almost transparent, they are highly elastic, easily compressible, rapidly produced, and are almost always external. In process of time, however, the primitive color of these tumors disappears altogether, in consequence of their cuticular covering becoming thickened and blended as a part of them.

Differential Diagnosis.—The writer having already plainly shown that the polymorphic excrescences of the anus and the external hemorrhoidal tumors differ essentially and completely, in their origin, formation, and structure; and as both the disease and the treatment involve considerations of much higher importance in the one case than in the other, he will therefore still continue to add further evidences to prove that these anal growths are not hemorrhoids, as they have been represented, and in attempting this he will endeavor to show too that this particular subject in controversy is not so unimportant and so trivial as some, who ought to know better, have represented it. Now, the first step which the writer will take for the further elucidation of this subject will be to show what the hemorrhoidal disease really and truly is, and also to give the etymology, signification, and application of the words hemorrhoids and piles. In order, then, to understand what the hemorrhoidal disease really is, a minute inspection of it in its origin must necessarily be made; for, in process of time, additional morbid changes with serious complications may take place, and which may completely alter the primitive state of it, so that a true diagnosis of it might be difficult to determine.

The writer holds and maintains that the disease which has been denominated hemorrhoids or piles is an inflammatory state of the hemorrhoidal blood-vessels themselves, especially of the arterial and venous capillaries in the inferior portion of the rectum, from some exciting cause, producing excessive relaxation of their parietes; and that this in brief is the essential, the primitive, or substantive disease, regardless of the cause or causes which produce it; and besides, he further maintains that this disease does not consist of either tumors alone or of hemorrhage alone, or of both combined; these do not constitute the affection, but are merely the effects or the consequences of it, and are to be considered as only accessory, accidental, or a more or less direct result of it, and can not therefore be made to characterize it; for it is a positive fact that neither tumors nor hemorrhage often exist in any stage of the disease, and in many instances neither one nor the other nor both ever appear during the whole attack; but authors generally ignore this fundamental fact, and present for treatment the symptoms, the effects, or the complications of hemorrhoids as the disease itself. With special reference to hemorrhage, it does not in any sense constitute the hemorrhoidal disease or any part of it, but may, when it occurs, be taken as an uncertain symptom of it. Indeed, bleeding, regardless of its source, is never a disease, but merely an evidence or a symptom of it—either of disease in the part itself from which it proceeds, or of disease in some remote part or organ; hence, no tumor, no hemorrhage whatever can justly be called hemorrhoids, unless in close and intimate connection with the morbid hemorrhoidal blood-vessels themselves. Now, these polymorphic anal excrescences have no intimate, no direct connection or communication whatever with the hemorrhoidal blood-vessels, whether diseased or not, and consequently are not hemorrhoidal tumors, for when such tumors present themselves they are always the result of the hemorrhoidal disease, consisting of a morbid condition of the veins or venous capillaries of the inferior portion of the rectum, and the tumors resulting from this cause are regular organized growths, sustained and supported by continuing in direct communication with the morbid vessel or vessels which caused them. Such tumors, as before observed, are consequent upon the effusion of blood from the morbid vessels into the cellular tissue of the part, where, from this blood and cellular tissue, organized tumors are sooner or later formed; for it must be admitted that all true hemorrhoidal tumors are imbedded or have their seat, when external, in the subcutaneous cellular tissue, and when inter-
nal, in the submucous cellular tissue. Indeed, the cellular parenchyma is never absent in true hemorrhoidal tumors, being essential to their very formation and subsequent development.

It is considered of sufficient importance here to give the names of some among the most distinguished men of our profession who held and maintained the cellular origin of all hemorrhoidal tumors. Their opinions are worthy of the highest credence because they were formed alone from actual dissection; Cullen, Kirby, Abernethy, Harrison, Récamier, Chaussier, Lisfranc, De Larroque, Ribes, and Richter. It is admitted, however, that there are a few equally distinguished authors who have taken different views of the origin of hemorrhoidal tumors. This particular subject has been thoroughly examined in the sixth chapter of the writer's treatise on the hemorrhoidal disease, published in 1884.

The writer has now very briefly and distinctly shown what he believes the true hemorrhoidal disease is; indeed, from the foregoing premises he holds that even the morbid relaxation, from whatever cause, of the hemorrhoidal veins and capillaries, both arterial and venous, is alone sufficient for the explanation of the phenomena of the hemorrhoidal disease. And he has also shown what he conceives the true hemorrhoidal tumors are, simple and isolated from all other tumors or excrescences, whether coexisting with them or not.

The Term Hemorrhoids.—The word hemorrhoids is derived from the compound Greek word ὁμορροϊς, which is formed from ὁμός, sanguis; and ὅρροις is derived from ὅρρος, fluo; consequently, it signifies a flux or a flow of blood—nothing more, nothing less. Now, this word, regardless of its etymology and signification, has been, and even now is, applied to all manner of affections, whether attended by hemorrhage or not; some of the ancients as well as the moderns, and even some present authorities, have applied the term hemorrhoids to vascular dilatations, varices, hemorrhages, tumors, and to cutaneous excrescences or vegetations situated about the anal orifice, etc. Indeed, there is no name of any disease in the whole medical vocabulary in which such unlimited license has been indulged in as in the promiscuous application of the word hemorrhoids. Isasmuch, however, as the blood-vessels of the rectum consist of the superior, middle, and inferior hemorrhoidal—so called by the ancient Greeks, doubtless in consequence of the frequent irregular hemorrhages from the rectum—no disease or hemorrhage should therefore have been denominated hemorrhoids unless it pertained exclusively to those vessels; for if the term hemorrhoids had heretofore been restricted to affections of the hemorrhoidal vessels alone, much obscurity, confusion, and perplexity in the use of it might have been obviated. Under the term hemorrhoids authors have confounded affections of every kind; they have used the term not only to signify every complication of the true hemorrhoids, but also of affections of an entirely different character; hence they have treated of hemorrhoids of the mouth, of the palate, of the throat, of the nostrils, of the ear, of the uterus, of the urethra, of the kidneys, of the bladder, etc. Now, upon this principle they might with great propriety lengthen this their already extended catalogue indefinitely, for there is no part of the body which a similar cause might not affect. It would be supposed that the ideas which the word hemorrhoids naturally suggests would never have permitted its application to those various affections above enumerated, whatever analogy might have been found to exist between them; for it should be observed that the term hemorrhoids, which is so defective and inappropriate in its ordinary application, is, if possible, decidedly more so when applied to the analogous affections of the uterus, the urethra, the bladder, etc. The learned Alberti calls all such examples extraordinary or displaced hemorrhoids (Dissertatio de haemorrhoidium insolitis visis, Hage, 1722).

With regard to the phrase hemorrhoids of the bladder, the writer will here give an amusing instance in which this expression was employed very dexterously. It is well known that the late M. Nélaton, physician to the late Emperor Napoleon III, used on a certain occasion, when treating him during his last illness, the expression vesical hemorrhoids in a very adroit manner. This very able and distinguished surgeon, believing that the emperor's disease was fungous tumors or excrescences of the bladder, or some other grave affection, and wishing to conceal from the friends of his imperial patient, as well as from his Majesty himself, the very serious nature and gravity of his malady, used, when strongly urged to give a diagnosis, the very ingenious euphemism hemorroides de la vessie, knowing very well that hemorrhoids were a disease whose nocuousness was familiar to every one.

The writer is well aware of the difficulty and the almost impossibility of ever reforming old names, or changing them for new ones, however absurd their signification and application might be. Instead, therefore, of exchanging the word hemorrhoids, the use of which has been sanctioned for ages, for one more expressive and comprehensive, as well as to make as little change as possible, or as the nature of the case will admit, the writer would respectfully suggest that the adjective form of the word should always be used, as hemorrhoidal disease, hemorrhoidal tumors, hemorrhoidal congestion, hemorrhoidal blood, etc. These terms have at least some reference to the seat of the disease or part affected of the same name, and on that account can be employed with much greater propriety than the word hemorrhoids can. The writer considers it proper to remark here that Hippocrates restricted the use of the word hemorrhoids solely to a flux of blood from the veins of the anus, and speaks of it as being an affection of the anus only. "Exercitaciones por oras unanum que sunt in ano hemorrhoidas vocant" (De Alimento liber). Galen also, like his great prototype, designated under the name hemorrhoids a flux or a flow of blood from the veins of the rectal portion of the large intestine (Definiciones medicae).

The writer could here add other able and distinguished ancients who held the same views. The error of these ancients consisted in considering the hemorrhage to be the real disease itself, an error which exists to some extent even at the present time; and furthermore, from the remotest antiquity to the present day, the word hemorrh-
rhoids has been used by the largest majority of authors, including medical lexicographers, exclusively to designate tumors of the rectum and anus, whether attended by hemorrhage or not, as the disease itself. The error of these authors consists in maintaining that the tumors are the disease. It will be perceived, however, that those who hold that the hemorrhage from the anus alone is the disease and those who declare that the tumors alone are the disease are both in error alike, yet their theory is more plausible and contrasts widely with that of those who apply the word hemorrhoids promiscuously to tumors or hemorrhage alike, in different parts of the body, as has been shown above.

The writer has now briefly exhibited the fact that authors have presented the symptoms or the complications of the disease called hemorrhoids—namely, either hemorrhage, vascular dilatations, varices, or organized tumors—as the veritable disease itself, whereas it can neither be characterized by bleeding alone, by vascular dilatations, varices, or by organized tumors alone, nor, indeed, by all these combined, for bleeding may occur without dilatations, varices, or organized tumors, and each one of them may exist independently of the other.

It seems to be proper here that something should also be said regarding the signification and application of the scriptural word emerods or emeroids, as adopted in the English version of the Hebrew Bible, which was ordered and translated under the auspices of King James I. The first mention of this word occurs in Deuteronomy, xxvii, 27, as follows: "The Lord will smite thee with the botch of Egypt, and with the emerods." The word emerods is evidently a corruption of the Greek word ἁμορροίος, and has the same signification—namely, a flux or a flow of blood. Now, the question arises, Does the word emerods correctly and truly represent the disease or plague which the Lord through Moses threatened the Jews if disobedient? Is it a correct rendering of the Hebraic word or words which Moses used to designate this affliction? Was this divine punishment to consist purely of a flowing of blood, as the word emerods denotes, or was it to consist of something else? According to the most profound authority—and authority is everything in a dead language—the Hebraic words Apholim and Tehorim are the words which Moses used in describing or indicating the threatened disease. These same words were used by Samuel, three centuries subsequently, in describing the same disease or plague which the Lord had inflicted upon the Philistines for taking the ark of the Lord, as recorded in the fifth and sixth chapters of the first book of Samuel.

It is agreed by the most approved authorities that the word Apholim means the disease, as tumors, swellings, or varices, and that the word Tehorim signifies the part affected, as the seat, the fundament, or the anus, and that both words used conjointly signify tumors, swellings, or varices of the fundament or the anus. The learned Gesenius translates Deuteronomy, xxvii, 27, into German, "Geschwiste am After"—that is, tumors or swellings of the anus (Hebräisch-Deutsches Handwörterbuch über die Schriften des alten Testaments. 8vo, Leipsic, 1810). This exposition is doubtless the true one, inasmuch as it corresponds exactly to the disease when attended by tumors. It is thus made evident that the Hebraic and the Grecian definitions of this disease do not agree in any one particular.

It is worthy of remark that there is no record or evidence whatever in the Bible to prove that the hemorrhoidal plague with which Moses threatened the Israelites was ever afterward visited upon that peculiar people as a divine punishment. But the Lord did inflict it upon the Philistines, as is graphically described by Samuel in the fifth and sixth chapters of his first book, as above stated.

The Term Piles.—Why the word piles, the plural of pile, should ever have been selected as a technical term to indicate the hemorrhoidal disease is difficult to imagine, for there is nothing whatever in its etymology and signification that is at all expressive of any property or thing appertaining to that disease. The word pile is from the Latin pilæ, a ball, and from the Greek πτας, a globe, a ball. This word can not, therefore, with any reason or sense of propriety, be applied to or used to designate any excrescences or tumors, regardless of their locality or whether they bleed or not, unless such are round or globular; hence it should never be employed to designate the hemorrhoidal disease, which does consist of tumors or excrescences; but those who maintain that it does can use it to distinguish all the round excrescences or tumors from all those that are not globular.

The name piles is misleading when used to designate the hemorrhoidal disease, and it would be far preferable to use a term having no signification at all, especially as we are told that the nomenclature of this disease is now so well understood and established that it is useless even to suggest any change in the application of the term. According to this notion, however, a word, as before observed, without any meaning whatever will answer just as well to denote a disease as a significant one, doubtless upon the principle that a rose is a rose and smells just as sweet under any other name. The truth is that in proportion to our knowledge of the seat and the nature of the disease will be our ability to give it a clear and expressive name which will at once denote it. The terms phlebitis, arteritis, appendicitis, proctitis, rectitis, iritis, cystitis, and cellulitis are clear and expressive names, denoting both the seat and the nature of the disease. But it seems useless to expend any more words on the misapplication of the word piles in this particular case, for there is no certainty that they will be heeded. It has always been said by some that medicine is not a science and can never be. Now, if this is really true, then let us at once endeavor to the best of our ability to approach as near as possible to the scientific pole; or, in other words, if we can not be scientific, then let us try and be as scientific as we can.

A recent author has classified the circumoral excrescences with the other external tumors as hemorrhoids, but, as they do not bleed, he on that account objects to the word hemorrhoids and prefers the term piles; but there is nothing whatever in that word which designates the absence of hemorrhage. Now, by comparing this author's substitution of the word piles for that of hemorrhoids and
From remote antiquity hemorrhoids have always been distinguished into bleeding or open, *hemorrhoides fluentes vel apertae,* and into blind, *hemorrhoides coecae vel non fluentes.* The Germans have the same division into bleeding, *fliessenden Hämorrhoiden,* and into blind, *blinde Hämorrhoiden.*

**Treatment of the Anal Excrecences.**—The surgical operation for the removal of these vegetations is so very simple that it scarcely deserves the name. It is important, however, in performing it not to include in it too much of the integument surrounding the anus; for, if the cuticle is too much encroached upon, stricture of the anus will be the result. The operation is performed by seizing each excrescence with a small forceps, drawing it out slightly, and snipping it with a scissors curved on the flat, or with the knife, and then dressing the cut like any other fresh wound.

It is important and essential in treating this affection to endeavor to discover the primary cause of it, and to treat or remove that, together with the effect, at the same time; for, after the removal of the excrescences, the cause which produced them, still existing, may again cause them to reappear. When the anal excrescences coexist with internal hemorrhoidal tumors, by the removal of these, those sometimes spontaneously disappear, as the writer has observed several cases of the kind.

The ancients, in treating this affection, employed severally the knife, the scissors, the actual, and the potential cauteries, and the écraseur; and beyond these several ancient measures we of the present day know no others in the treatment of this affection. Some of the ancient methods, however, of extirpating these excrescences were indeed shockingly rude—such as pinching, crushing, or tearing them off, etc.; such measures might therefore be appropriately denounced torsion, avulsion, avulsion, or écразеment. Hippocrates himself advised and adopted the very unique method of removing these excrescences, when they were of a soft or friable nature, by pinching them off with the fingers, and he makes a long and very curious statement of the manner in which the operation should be executed, all of which is presented in his special classical treatise, Περὶ Ἀνορρόηδος (De Hemorrhoidibus).

**The Medical Treatment of the Hemorrhoidal Disease.**—The medical or curative treatment of the hemorrhoidal disease is scarcely ever mentioned or alluded to by authors; their whole attention seems to be directed to the surgical treatment of the hemorrhoidal tumors, which are not the disease, but the mere offspring or offshoot, as has been shown; so that by removing the tumors alone the morbid blood-vessels which produced them would still remain to repeat them. Some of the rectal specialists, however, say positively that by removing the tumors alone by knife, ligation, or Smith's clamp the cure is radical. But in order to make the cure radical by surgery alone, the morbid blood-vessels must also be removed, either by knife or scissors, or both; such operation is now advised and performed by a few, and, however bad it is, it at least is consistent in that it removes both the cause and the effect at the same time.

The writer not only believes but knows that the hemorrhoidal disease can be cured medicinally either before or after tumors have formed; but when they coexist it is all-important that the tumors should be removed surgically by either ligature, knife, or clamp, unless the successful treatment of their primary cause should have resulted in their removal. Indeed, when this disease is attended with tumors which are the effect of it, by curing the disease the effect may cease, upon the principle that by the removal of the cause the effect will cease; but the effect of a certain cause of long continuance may itself sometimes become a disease, and exist independently of the cause or disease which first produced it, so that the removal of the original cause in such a case will not remove the original effect, which has now itself become an independent entity. When this is the case both the cause and the effect should be successfully treated conjointly before the cure can be pronounced radical.

It has already been shown that the hemorrhoidal disease consists in part of a morbid relaxation of the veins and venous capillaries of the hemorrhoidal plexus, by which their capacity is increased and their contractile power diminished, so that they readily admit of overdilatation and become engorged with blood or some of its elements. The principal indication, then, in the medical or curative treatment of this disease is to restore the lost tone and activity of the morbidly relaxed, debilitated, and engorged vessels, and, inasmuch as these can not unload themselves by reason of their asthenic state, they should be assisted to do so by the exhibition of such internal medicines as would tend to increase their contractile power and action, and thus enable them sooner or later to force out their superfluous contents, as well as to prevent any undue quantity of fluids from entering them. To fulfill this indication we have in belladonna, aconite, nux vomica, and ergot valuable remedies if properly directed, as the writer can most favorably testify; he has also used the iodide of potassium in large doses with equal success in the cases of the peculiar internal hemorrhoidal tumors which very much partake of the navoidal structure and resemble erectile tissue, and have been denominated "aneurysm by anaeromosis."

Sometimes the vascular engorgement of the veins and capillaries is the result merely of a neurosis, and when this is the case the rational treatment should, of course, consist in the restoration of the nervous energy and of the proportionate caliber of these vessels.

One of the therapeutic measures which the writer has employed for a number of years with excellent results is dilatation of the anus and anal canal by the use of bongies of different sizes once or twice daily. If this treatment is judiciously executed before extravasation and organized tumors are formed, it may prove the means of destroying the morbid condition of the blood-vessels and overcoming any undue contraction of the anal sphincters, and thus prevent the further progress of the disease. The influence of the bongies in removing the morbid sensibility and in relaxing the rigidity of the sphincters, as well as facilitating the

THE PROGNOSIS OF OPERATIONS UPON THE MAStOID PROCESS OF DIABETIC PERSONS.*

By ALBERT H. BUCK, M.D.,
CLINICAL PROFESSOR OF THE DISEASES OF THE EAR
IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK;
CONSULTING AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY
AND THE PRESBYTERIAN HOSPITAL.

From Professor Kuhn's and Dr. Körner's articles in volume xxix of the Archiv für Ohrenheilkunde (1890) I have gleaned the few facts which follow.

Medical literature contains very few reports of mastoid disease occurring in persons affected with diabetes mellitus. Apparently the earliest case on record is that reported by Toynbee (Diseases of the Ear, London, 1860). This was a case of a diabetic patient, twenty-nine years of age, who contracted an acute inflammation of the right middle ear, which spread to the mastoid process, caused severe pain in this region, and eventually terminated fatally after the development of vertigo and coma. At the post-mortem examination extensive caries of the mastoid process and perforative ulceration of the lateral sinuses were found.

The next earliest report is that published by W. Roser in the Deutsche med. Wochenschrift, 1880. This was a case of "diabetic caries of the mastoid process" in a man seventy years of age. An immediate operation was advised and was to have been performed on the following day, but during the night the patient suddenly died. The immediate cause of death was not ascertained.

* Read before the American Otological Society at its meeting in New London, July 16, 1895.
In the following year Raynaud (Annales des maladies de l’oreille, May, 1881) published the report of a case of acute inflammation of the middle ear in a diabetic patient (male) forty-seven years of age. The onset of the attack was characterized by intense pain in the ear and the escape of quite a large amount of blood from the external auditory canal. The patient died twenty-three days later under manifestations of great weakness and prostration. At the post-mortem examination the mastoid process was found to be extensively curiously, and filled with pus and blood.

In Frerichs’s classical work on diabetes, published in 1884, the statement is made that out of fifty-five post-mortem examinations of diabetic patients who had died from some disease of the nervous system, there was only one in which “otitis interna, with caries of the mastoid process and thrombosis of the lateral sinus (woman, thirty-nine years of age),” was found.

Kirchner reports (Troisième Congrès international d’otologie, Bâle, 1885) a case of well marked acute mastoid inflammation that occurred in a diabetic patient (male) twenty-two years of age. The symptoms were severe pain in the mastoid region, evidences of mastoid peristitis, and beginning cellulitis along the course of the sterno-cleido-mastoid muscle. An operation was performed, and the patient died five days later. At the post-mortem examination it was found that the caries had advanced as far as to the sigmoid fossa.

Schwabach (Deutsche med. Wochenschrift, 1887) reports the case of a man, forty-three years of age, who had been affected with diabetes mellitus for a period of six years, and who suddenly began to suffer from a violent pain in the ear due to an acute inflammation of the middle ear. The pain soon extended to the mastoid region. Then followed quite a long period of comparative freedom from pain in the affected locality. Finally, the pain again became severe, the facial nerve became paralyzed, and an operation upon the corresponding mastoid process revealed the existence of extensive bone caries. Bad smelling pus filled the pneumatic cells in all directions. The facial paralysis gradually disappeared, and the wound healed only after the lapse of several months. Two years after he had recovered from the ear trouble he died from an attack of cerebral apoplexy.

Moos’s case (Deutsche med. Wochenschrift, 1888) was that of a man, fifty-five years of age, who had had diabetes mellitus for a period of three years, and in whom symptoms of mastoid disease had developed five months previously. Operative interference was begun in the usual locality, but there was such a profuse escape of blood that it was thought best to abandon the operation. Seven days later an abscess was opened in the temporal region and, three weeks later still, another one was opened. Complete recovery followed in the course of a few weeks. Moos examined the pus which escaped from the middle ear, in this case, and found it to contain both the Streptococcus pyogenes and Frerichs’s diplococcus.

To the preceding brief reports of diabetic mastoid cases Kuhn adds the histories of two of his own cases. In the first of these (male, fifty-four years of age, and of apparently robust health) the patient had had diabetes mellitus for about a year. After a severe cold he began to suffer from pain in one ear. Seven days later evidences of mastoid disease were observed. Chill on the twenty-second day of the ear attack. On the following day he had a decided hemorrhage from the affected ear, the blood being of a noticeably dark color. After the hemorrhage the purulent discharge, which previously had been profuse, ceased altogether. At the same time the patient became very dizzy. Soon afterward he had two chills, and then general convulsions; a few hours later he became comatose and died. At the post-mortem examination extensive caries of the mastoid, with ulceration of the dura mater and also of the wall of the lateral sinus, was found.

Kuhn’s second case was that of a man, fifty years of age and seemingly in good general health, in whom first one mastoid and then the other became involved in acute inflammation. An examination of the pus that escaped from the middle ear revealed the presence of large numbers of both the Streptococcus pyogenes and the Staphylococcus albus. Fistulous openings developed in both external auditory canals and the relief afforded by this additional drainage eventually proved to be sufficient. At all events, no serious attempt was made to penetrate into either mastoid process, and yet at the end of a few weeks both ears had ceased to discharge and the hearing had in large measure been restored.

In the same volume (xxix) of the Archiv für Ohrenheilkunde in which Dr. Kuhn furnishes the facts which I have repeated here in a condensed form, I find the report, by Dr. Otto Körner, of another diabetic mastoid case. The patient was forty-seven years of age and of previous good health, and the diabetic condition was only discovered after the mastoid disease had become well established. The usual operation was performed and the patient made a fairly good recovery, the external wound healing completely thirteen weeks later.

The ten cases which I have reported here in the briefest possible outlines comprise all the published instances of mastoid disease occurring in diabetic persons which I have been able to discover. I ought to add, however, that my search has not been a thorough one by any means; but yet I believe that it has been sufficiently thorough to establish one or two facts of greater or less practical importance—viz., first, that disease of the mastoid process is likely to be a more serious affair in persons affected with diabetes mellitus than in those who are in an ordinarily healthy condition; and second, that the destructive processes within the temporal bone tend to advance at a more rapid rate in diabetic than in non-diabetic individuals.

Out of the ten cases reported above, there were seven in which operative interference was not resorted to. Five of the seven patients died—a mortality of seventy-one per cent. Three out of the ten were operated upon, and only one of these died—a mortality of thirty-three per cent. The four whose cases I shall report farther on: were all operated upon. Two of these died and two recovered. Consequently, when these four cases are added to the other three,
the mortality rises from thirty-three to forty-three per cent. The prognosis, therefore, in these diabetic mastoid cases is clearly not favorable. But if any one who is interested in the subject will take the trouble to read the detailed histories of the cases reported in the articles of Kulh and Körner, and also those which are appended to this article, I think he will agree with me that in nearly every instance the operation was postponed until a comparatively late date. I fully believe that later statistics, covering a larger number of cases, will warrant the giving of a more favorable prognosis than the few data now at our disposal permit. But if my expectations are to be realized, it is imperative that mastoid operations upon diabetic persons shall be performed at a comparatively early stage of the disease in the temporal bone; that is, before the lateral sinus or the dura mater has become seriously involved.

Case I.—Male, forty-seven years old, a physician, and somewhat emaciated in appearance. On the 16th of April, 1895, he used the nasal douche with warm salt water. Shortly afterward pain developed in the left ear. Paracentesis of the membrane tympani was performed by his son on the following day. Only temporary relief from the pain. Free discharge from the middle ear. Pain soon increased in severity, and involved the entire side of the head, although the patient felt it chiefly in the mastoid region. On the 10th of May I saw him for the first time. There was then a little tenderness on pressure behind the left ear, but no redness or edema of the skin. The discharge from the ear seemed to be abundant, and was distinctly purulent in character. Membrana tympani red and infiltrated. The posterior and upper cutaneous wall of the inner half of the canal drooped perceptibly.

On inquiry I ascertained that the patient had been affected with well marked diabetes mellitus for a period of at least two years, and that during the past year he had lost fully forty pounds in body weight.

Local antiphlogistic measures and rest at home were tried for eight days in the vain hope that the mastoid inflammation might thereby be relieved. Complete relief from pain was obtained, but the discharge still continued to be purulent in character and copious, the progress of the upper cutaneous wall still persisted, and there was no perceptible change in the degree of tenderness observed behind the ear.

The operation was performed on the 18th of May, under ether anesthesia. The cortical portion of the mastoid process was found to be reduced in thickness to a mere shell of bone. Pus (iodoform) and granulation tissue filled, apparently, the entire process. After removing the contents of this large cavity, I proceeded to scrape its walls with a small and rather dull-edged Volkman’s spoon, in order to make sure that no disced bone or necrotic membrane should be left behind. While I was doing this, with the slender Volkman’s spoon held between my thumb and fingers as one usually holds a pen, I felt something give way on the inner and posterior portion of the cavity, and instantly there was an abundant but quiet welling up of very dark blood. From this circumstance I knew at once that I had broken through what was doubtless the ulcerated (but not yet perforated) wall of the sigmoid flexure of the lateral sinus. A temporary stuffing of simple gauze was inserted, and at the end of a few minutes it was removed in order that one of iodoform gauze might be introduced in its place. The temporary stuffing, it was found, had entirely checked the hemorrhage.

May 19th.—Patient has constant nausea and is unable to keep anything on his stomach. Temperature normal. No chilly sensations. 20th.—Iodoform plug removed from the cavity in the mastoid process. No further bleeding. Wound looks healthy. Some headache. Iced milk retained, but nausea persists. Temperature still normal. Wet bichloride dressings, and wound douched once a day with a 1-to-2,000 bichloride solution. 22d.—Wound surface has a dirty appearance. The few granulating spots look unusually pale, as if the parts lacked vitality. Bichloride solution used in douching the wound to be increased in strength to 1 to 1,000, and the douching itself to be employed twice instead of once a day. The temperature still continues to be normal, the pain in the head has gone, and the nausea is slowly becoming less marked, but the patient’s general strength is evidently diminishing.

On the 29th of May, under manifestations of increasing weakness, the patient passed into a comatose condition, with rapid breathing, and died before night. There were no chills, elevation of temperature, or anything else to indicate that the opening in the lateral sinus had in any way aggravated the situation. His death seemed to be due to his diabetic condition, aggravated unquestionably by the disturbing effects of the administration of the ether and by the shock of the operation.

Case II.—Male, about fifty-five years old, and somewhat emaciated in appearance. For a period of six years he had had diabetes mellitus. On or about December 10, 1891, he began to experience some pain in the left ear, followed soon by a discharge, which gradually became quite abundant. From the 16th of December until January 23, 1892, the day on which I was first called to see the patient, he was never free from pain in or about the ear for more than a few hours at a time, and toward the end of this period the pain seemed to be located chiefly behind and above the ear. On examination I found that the skin covering the left mastoid was normal in appearance, but there was appreciable tenderness on pressure over the central and lower part of the process. The discharge was distinctly purulent in character and abundant. As the patient had been attending to business, I advised (tentatively) rest at home, systematic douching of the external auditory canal, and frequent hot positions.

On the 5th of February I found that the discharge from the ear had become more profuse, and there were evidences of the escape of infective material into the tissues on the side of the neck below the mastoid. There was also redness and infiltration of the skin behind the process, toward the occipital region. On the 6th of February ether was administered and I established a free opening into the mastoid process, removing all softened bone and granulation tissue, but finding no pus at any point. In every direction I found a high degree of hyperemia, and the oozing of dark venous blood was so active and so constant that it would have been impossible to distinguish any but a large and separate collection of pus.

The subsequent progress of the case, up to February 12th, presented no features of special interest. The redness and infiltration of the skin between the mastoid process and the occipital region did not subside, but rather increased a little; and yet, when his physician visited him on the morning of the 12th, the patient seemed to be getting on particularly well. Nevertheless, six hours after this visit, he began to complain of headache and a sensation of chilliness, and gradually sank into a comatose condition, with a pulse of 130, a temperature of 104° F., and rapid breathing. Death occurred on the same day.

In looking back upon this case in all its aspects, I do not feel at all sure that the patient died of diabetic coma, pure and simple. It is quite as likely that a periphlebitic
collection of pus finally found a way of escape for itself through the eroded wall of the lateral sinus, and so induced the chilly sensation experienced by the patient on the last day of his life, the rise in temperature, the coma, and the rapid breathing. The redness and swelling of the integuments just behind the mastoid, taken in connection with the high degree of hyperemia observed in every part of the body of the mastoid process, seem to me, as I remarked in the paper which I read before this society last year, to warrant a diagnosis of active phlegmonitis in the sigmoid fossa of the temporal bone.

Case III.—Male, forty-nine years of age, and, up to the time of the present illness, strong and apparently healthy. Early in March, 1895, he had an attack of what seemed to be the grippe. His right ear soon became involved, and he experienced a great deal of pain in it. At the end of two days a discharge made its appearance, and he then obtained some relief from his earache. From that time to the day on which he called to see me (April 10, 1895) the discharge from the ear had been constant and abundant. The pain had come in paroxysms and at times had been severe. During the preceding two or three days there had been some redness, swelling, and tenderness of the skin behind the right ear, and he had been unable to obtain more than a few snatches of sleep on account of the severity of the pain, which by this time involved the entire right side of his head. His urine was examined and found to be loaded with sugar. He was questioned in regard to the quantity which he habitually passed, but apparently he had not voided a greater amount than might fairly be termed normal. An examination of the ear revealed the fact that the upper and posterior cutaneous wall of the right external auditory canal was prolapsed to such a degree that it was not found possible to obtain a view of the drum membrane. The body temperature was found to be 99° F., and the pulse 102, full and regular; but the patient looked and felt decidedly ill. There were very decided evidences of mastoid perichistis.

On the 11th of April ether was administered as an anesthetic, and the usual operation was performed upon the affected mastoid process. The surface of the exposed bone showed, near its centre, the shaved-beard appearance indicative of the plugging of a number of small blood-vessels in the cortical portion of the bone. Pus and gas bubbles were found at a very slight depth from the surface. The odor which quickly filled the air in the immediate vicinity was that of sulphured hydrogen with a certain sweetish flavor added to it. In all directions pus and dead bone were found, and from the antrum and immediate surroundings the flow of dark blood was unusually active. In the immediate vicinity of the sigmoid fossa I found the bone perfectly black and softened. I carefully scraped away all this affected bone until I reached the hard cortical substance which constitutes the immediate bony support of the lateral sinus, and as this seemed to be natural in consistence, although somewhat darker than it should be, I decided not to break through into the sigmoid fossa. The usual dressings were applied after the mastoid excavation had been thoroughly irrigated with a 1-to-2,000 bichloride solution and then dusted with a powder composed of one part of iodiform and four of boric acid (as suggested by Macwes). During the first four days following the operation the patient experienced a good deal of pain throughout the right side of the head, and all the soft parts behind and above the wound, and extending to a considerable distance from it, presented an angry and swollen appearance, almost suggesting erysipelas. But the body temperature did not rise above 100° to 10° F. Toward the end of this period I evacuated some thin pus from beneath the scalp above the wound, and on the next day (April 17th) I found the patient almost free from pain and with considerably less inflammation around the wound. The urine was examined a second time and found still to be loaded with sugar.

From the 17th of April onward the patient made a rapid recovery, without drawbacks of any kind. On the 21st he returned to his home in the country. A third examination of his urine was made about one week or ten days later, and sugar was still found in it in abundance. On the 19th of May he called to see me, and I found that the wound had become reduced in size to a mere granulating orifice. It probably healed entirely in the course of the following four or five days.

(Through the courtesy of Dr. William B. Coley, of this city, I am able to give the more important facts relating to a fourth patient whom I saw with him in consultation.)

Case IV.—Male, sixty-two years of age, rather infirm in his general appearance and gait, and afflicted with diabetes mellitus during the past four years. In June, 1894, he experienced pain first in the left ear and then, on the following day, in the right. For a period of about four weeks he suffered a good deal from pain, chiefly in the right ear. Paracentesis of the right membra tympani afforded considerable relief. At the end of seven or eight weeks he noticed that the skin behind the right ear was beginning to be tender on pressure and somewhat swollen. In a few days it was found necessary to open an abscess in this locality. This afforded further relief from the pain; and from that time until the 26th of October, when I saw the patient in consultation with Dr. Coley, he got along fairly well. Both ears continued to discharge, and a fistulous opening persisted behind the right ear. On examination, I found that on both sides there was well-marked prolapus of the upper and posterior cutaneous wall of the external auditory canal (inner half), with a congested and infiltrated membra tympani. The fistula behind the right ear was explored with a probe, but no denuded or roughened bone was felt. The neighboring soft parts were markedly infiltrated. On the left side the mastoid integuments were also infiltrated, and the tenderness on pressure extended backward beyond the limits of the mastoid process.

On the 27th Dr. Coley operated on both mastoid processes and evacuated pus from both. The patient experienced no unpleasant effects from the prolonged administration of an anesthetic (ether), and soon regained a fair measure of health and strength.

At the present date (June 17th) I am informed that under a modified diet the patient has regained his health to a remarkable degree, and no longer exhibits sugar in his urine. The ears give him no trouble whatever, but the wound behind the left ear has not absolutely closed, although it now looks as if this might occur at any moment. The wound behind the right ear healed last March.

INTUBATION, WITH FORCED DILATATION OF THE LARYNX LASTING ONLY A FEW MINUTES, FOR DIPHTHERITIC AND CROUPOUS LARYNGITIS.

By LOUIS BORS, M.D.

The larynx of a child is, in consequence of its anatomical structure, of its ligamentous connections, and of its cartilaginous parts, quickly and easily dilated. The most important supports of the laryngeal skeleton, the thyroid
and the cricoid cartilages, are narrower anteriorly and laterally, and consequently of a weaker structure, than their posterior parts, which adjoin the esophagus. The thyroid, crico-arytenoid, and hyo-thyroid ligaments in the upper space of the larynx give very favorable conditions for dilatation, also the crico-thyroid and the crico-tracheal ligaments in the inferior section of the larynx. The soft tissues surrounding the larynx, such as muscles, arteries, and connective tissue, being covered only by skin, are easily compressed forward and sideways, but the posterior parts are not compressible, on account of the vertebral column. Dilatation of the larynx is therefore produced by stretching the ligaments and by lateral pressure on the surrounding parts.

Aphonia supervening in such cases at an early date proves that in diphtheritic and croupous laryngitis the vocal cords and the ventriculi Morgagni first cause the stenosis. This also proves that in false croup small mucous deposits on the vocal cords may give rise to asphyxia, which ceases, however, as soon as the deposits are cast off. Consequently it will not be difficult in most cases to arrest the stenosis by dilating the tissues around the vocal cords.

The diphtheritic and croupous exudations form superficial membranes of different lengths and thicknesses, and they are deposited in and on the mucous stratum and may quickly reduce the lumen. These exudations do not adhere to all sections of the mucosa with the same tenacity. They adhere more rigidly to the base of the epiglottis beneath the vocal cords; they become lodged in the mucosa because these parts are without glands, and because the submucosa is only loosely connected with the muscular stratum below and forms folds. The mucosa is covered with pavement epithelium. Beneath the vocal cords, as far as the first ring of the trachea, the mucosa is lightly connected with the inferior layer; it forms no folds and is covered with ciliated epithelium. The exudations adhering only loosely and superficially to the mucosa, they are therefore easily separated.

The danger arising from asphyxia in consequence of diphtheritic or croupous laryngitis has hitherto been checked by catheterism, tracheotomy, or intubation with more or less success, according to other disturbances in vital organs which threatened to give rise to negative results after operations.

The purpose of forced dilatation is to re-establish in a few minutes the lumen of the larynx which is more or less obstructed by false membranes and mucous matter adhering to it. After the introduction of the cannula the loose membranes are expectorated with the mucous matter covering them; the membranes adhering to the mucosa are loosened thoroughly or partly by forced dilatation with the cannula; by pressing the membranes against the wall of the larynx, which diminishes them in thickness, and by quickly opening and closing the cannula several times, they become loosened or separated from the inferior layer, and expectoration occurs shortly afterward.

In rare cases the membranes are reproduced within twelve or twenty-four hours and again give rise to asphyxia. In the majority of cases restored respiration is coincident with a reduced new formation of membranes; in some cases they develop in a few parts of the larynx, but are expectorated by the vigorous coughing of the patient, who now breathes more freely and can be better nourished. There are, however, cases in which repeated dilatations are indispensable. From my own experience I can state that the growth of false membranes seldom occurs more than twice, but should it do so no physician ought to abstain from applying forced dilatation for a few minutes every two hours and a half for two or three days.

Up to the present time, asphyxia and pronounced cyanosis have been considered by most physicians as the proper conditions under which to carry out tracheotomy or intubation. I should give the preference, however, to early action when stenosis appears with its alarming symptoms, leading to retraction of the neck and of the scrobiolus cords, and thus often prevent pneumonia, bronchitis, emphysema, and stagnation of blood in the kidneys, which we are accustomed to consider as fatal complications, although, in fact, they are but the consequences of stenosis of long duration.

The instrument consists, first, of one three-bladed, jointed, dilating cannula; second, of a bent shaft; third, of the introducing handle. It is dilated as follows: After introducing the cannula into the larynx, the screw situated under the handle of the instrument is turned to the right, drawing the inner blade of the cannula to one side and enlarging its diameter without using force in dilating. The closing of the cannula for removal is as simple as its dilatation, by reversing the screw under the introducing handle. There are three sizes of these formidable dilators for diphtheria and croup, the lumina (or inside diameters) of which are, when closed, respectively 2.5 mm., 4 mm., and 5 mm. The obdurator has three femur in its lower distal extremity which prevent asphyxiation in the introduction. The instrument is made in the most satisfactory manner by Messrs. George Tiemann & Co., of New York city.

The manipulation is harmless and painless, and requires only a few minutes in the application. The indications for forced dilatation of the larynx in syphilis and in other cicatrices will be treated of in another paper.

A New York Physician in Practice in London.—Dr. Allan McLane Hamilton, of New York, is practising in London for the summer (May, June, and July) at No. 14 Chesterfield Street, Mayfair.

Changes of Address.—Dr. Albert S. Ashmead, to No. 270 West Forty-third Street, New York; Dr. Ervin A. Tucker, to No. 62 West Forty-eighth Street, New York.
ELECTRICITY AS A DEATH-DEALING AGENT.

The account which elsewhere in this issue we reprint from last Saturday's Sun of the resuscitation of a man who had been rendered unconscious and apparently lifeless by a shock from an electric dynamo, and remained in a state of apparent death for close on to an hour, whatever allowance may have to be made for exaggeration, is calculated to give rise to reflection. In the first place, it makes us hope that the victims of lightning-stroke may in a fair proportion of instances be brought back to life if timely and well-executed measures are brought into play, especially artificial movements of respiration and rhythmical tractions on the tongue. M. d'Arsonval has, if we are not mistaken, laid great stress on the possibility of such efforts being successful and on the duty of reshorting to them, and it seems that his teaching has made such an impression even on men outside the medical profession as to lead the officers of the electrical company in Rochester, on whose premises the resuscitation referred to is reported to have occurred, to have their workmen drilled in the manipulations recommended by him. If only an occasional life is saved by following M. d'Arsonval's precepts the result will be a decided gain to humanity, but if success is achieved in a few cases modifications of the procedures or greater precision in carrying them out will doubtless soon raise the proportion of successful instances to the maximum attainable.

Another thought that will inevitably rise up before physicians is not so gratifying; it is that of the heightened probability given by the occurrence to the theory that men who are supposed to be put to death by electricity, under judicial sentence, in the State of New York are simply shocked into a condition of suspended animation that slowly ends in real death, even if the shocking event does not sometimes occur of their final taking off being accomplished by the autopsy that is so promptly performed. It is a revolting thought, but it is one that our humanity dare not shirk. It seems to us that the alleged advantages of electrical execution will have to be reconsidered most seriously. This journal has never admitted their reality, and now more than ever we feel it our duty to call upon the law-making power to use all diligence to ascertain if it has not made a horrid mistake while acting under the false light of supposed progress. If the death penalty must be inflicted, by all means let it be done by the executioner in the course of his duty, and not left to be done unwittingly by the pathologist. We make no statement that it ever has been done by him, but we see not how to escape the doubt lest it may have been, or lest it may be again if the practice of making over-prompt dissections of executed criminals is kept up. The whole matter of the manner of conducting executions in the State of New York ought, in our opinion, to be most carefully systematized by a body of men possessed of the necessary knowledge and clothed with sufficient authority.

ITEMS, ETC.

Society Meetings for the Coming Week:

MONDAY, July 1st: Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, July 2d: Buffalo, N. Y., Medical and Surgical Association; Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Society of the County of Broome (quarterly), N. Y.; Hudson (Jersey City) and Union (quarterly), N. J., County Medical Societies; Chittenden, Vt., County Medical Society; Androscegin, Me., County Medical Association (Lowiston); Medical Society of the University of Maryland (Baltimore).

WEDNESDAY, July 3d: Medical Society of the County of Richmond ( Stapleton), N. Y.; Bridgeport, Conn., Medical Association.

THURSDAY, July 4th: Society of Physicians of the Village of Canandaigua; Brooklyn Surgical Society; Cuyahoga County, O., Medical Society (Cleveland); Washington, Vt., County Medical Society.

SATURDAY, July 6th: Clinical Society of the New York Postgraduate Medical School and Hospital; Miller's River, Mass., Medical Society.

Proceedings of Societies.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Ninth Annual Meeting, held in Niagara Falls, on Tuesday and Wednesday, May 28 and 29, 1895.

The President, Dr. L. Bolton Bangs, of New York, in the Chair.

Tuberculosis and Neoplasms of the Bladder: Surgery or Hygiene?—The President first reported three cases of tuberculous of the bladder which he stated were typical of many in which hygienic treatment was followed by very beneficial results. Vitalization of tissue was what these patients needed, and they required at least two years of good hygienic residence in a temperate climate; besides climate, they needed occupation, for cænus seemed to be almost as deteriorating as confinement to the house. Surgical traumatism produced by overzealous efforts to relieve local symptoms seemed to result in more harm than good. Such efforts were apt to put the unhappy patient still further below par and facilitate the development of other tubercular foci, either in the same organ or in a distant one. It was not necessary to enter into the question of whether the infection was an "ascending" or a "descending" one; the bacilli were in the individual's blood, and were only waiting for a local congestion (following some form of irritation) in order to lodge and proliferate.
After faithful and zealous efforts to relieve the local symptoms of these cases by surgical interference, the speaker had been forced to the conclusion that the less instrumentation we resort to, the better. In the gonito urinary tract, as elsewhere, the best defense of the tissues against the invades of the bacilli, and that which finally effected a cure, was to be attained only by enabling the body to surround the tubercular deposits with a layer of healthy connective tissue. He expressed the opinion that this could be done in no other way than by improving the resisting power of the individual.

Dr. Bangs next referred to a class of cases in strong contrast to the foregoing, but in which the possibility of a cure also depended upon their early discovery—namely, malignant diseases of the bladder. Unfortunately, in these cases many of the early symptoms were overlooked, or, if recognized, were misunderstood. The patients themselves, because of the insidious onset of the disease, became acustomed to their first symptoms and usually did not seek the advice of their medical attendant until the affection was well advanced. The speaker then reported three cases of malignant disease of the bladder, and stated that he contrasted these two groups in order to present for discussion the points that incipient cases of tuberculosis of the bladder should be subjected to hygienic rather than surgical treatment, and that in the incipient stages of vesical neoplasms early surgical treatment of the most radical kind should be instituted.

Dr. Joux P. Buxson, of St. Louis, said he was entirely in accord with Dr. Bangs regarding the treatment of these tubercular cases. In tuberculous cystitis perineal drainage was not to be recommended. In two of his cases the perineal wound had become infected and had never healed. The suprapubic route was altogether to be preferred when drainage was to be resorted to at all in these cases. An early diagnosis was of the utmost importance, and was possible, perhaps, earlier than had been intimated in the paper. Careful examination of the prostatic urethra by means of the finger in the rectum, and repeated searches for the bacilli in the urinary sediments, would help us. When a suprapubic incision was deemed necessary, experience had led him to make the opening as high and as far away from the vesical outlet as possible, so as to have a direct drainage channel and keep the tube away from the vesical outlet, which was the most sensitive part of the bladder.

In cases of vesical neoplasms the symptoms frequently came on late. If the new growth was situated toward the fundus, or at any considerable distance away from the vesical outlet, there was no reason why there should be any symptoms of its existence for a considerable length of time, and the first symptoms was apt to be hematuria. The speaker said he was not so optimistic as the reader of the paper regarding the benefit to be derived from an early operation in cases of neoplasms of the bladder. He had never yet seen a case of papilloma of the bladder, supposed to be benign, which had not proved to be malignant and destroyed the life of the patient.

Dr. Gardner W. Allen, of Boston, reported a case of tuberculosis of the bladder, with very pronounced symptoms, which had been cured by hygienic treatment.

Dr. Brasford Lewis, of St. Louis, reported a case of tubercular cystitis in a farmer from Kansas. The patient had come to St. Louis, and there, under supporting treatment, rest, and the use of ergotic and cod-liver oil internally, the urine, which had been cloudy for three years, had cleared up, and the man had gained about twenty pounds in weight in three months.

Dr. Buxson said that in these cases he had observed much benefit from the use of the simple hypophosphites. Cod-liver oil had not been particularly serviceable. He had seen no benefit from the malt preparations, and ergot had not in any way helped his patients. In the early stages of the disease he had seen the frequency of urination relieved by the internal administration of the oil of yellow sandalwood.

Dr. Eugene Fuller, of New York, said he agreed with Dr. Bangs that hygiene was the most important factor in the treatment of these cases. Alcohol, in some form, was often of service.

Dr. George Cheesmore, of San Francisco, expressed the opinion that the pain complained of by these patients was very frequently due to the methods of search employed in endeavoring to discover the cause of the trouble. As a routine treatment, washing of the bladder was not to be recommended, particularly in tubercular cases. He agreed with Dr. Bryson that an early operation in cases of malignant growths of the bladder did not always effect a permanent cure.

The President said that, while he was willing to admit that the cure of malignant disease of the bladder was still a problem, the success he had obtained by operating in cases of so-called papilloma of the bladder warranted him in expressing the belief that such cases were curable by early operative interference.

**Hematuria.**—Dr. William K. Otis, of New York, read a paper on this subject. After detailing a number of chemical tests to demonstrate the presence of blood in the urine, the author stated that the actual presence of blood might also be determined by the use of the spectroscope; microscopes having a spectroscopic eyepiece were especially adapted for this purpose. When the existence of hematuria had been definitely determined, the next important step was to ascertain as accurately as possible in what portion of the urinary tract the lesion from which the hemorrhage emanated was situated. When it was situated in the anterior urethra, between the meatus and the compressor urethrae muscle, if the blood was sufficient in amount it would exude from the meatus or might be pressed out by stripping the urethra with the finger. If the urine was passed in two portions, the first only would contain blood. When the hemorrhage came from the posterior urethra, between the compressor urethrae muscle and the internal sphincter of the bladder, blood would not exude from the meatus, and, if the bleeding was sufficiently large in amount, the pressure would overcome the lesser resistance of the internal sphincter and the blood would flow back into the bladder, making it difficult to decide whether its source was the bladder or the posterior urethra.

In most of the cases where the bleeding came from the posterior urethra there was considerable urgency in urination, although occasionally this symptom was absent.

If the point of hemorrhage was situated within the bladder the entire urine therein contained would be intimately mixed with blood, and if the hemorrhage was profuse clots might form which had a certain diagnostic significance if they were too large to have passed through the ureter. Some authors considered the color of the urine an indication of the origin of the hemorrhage, but this varied so greatly under different conditions that it was unreliable and was of but little value in arriving at a diagnosis. Microscopic examination of the urine might show evidence of the presence of some new growth in the bladder, while on the other hand the detection of casts containing blood-corpuscles indicated that the lesion existed in the kidney.

Should the examination of the urine fail to reveal the source of the hemorrhage, we might proceed to the direct examination of the bladder itself by carefully washing out the organ through a rubber catheter by means of a hand syringe, and then inject a few ounces of clear fluid and withdraw the catheter just far enough to prevent the fluid from escaping; after a few mo-
ments the catheter was to be re-introduced, and if the fluid returned mixed with blood the haemorrhage was probably vesical in origin.

The resorption test, made by introducing a solution of potassium iodide into the bladder and shortly afterward testing the saliva for free iodine, was also extremely valuable and satisfactory for the purpose of determining if a lesion existed within the bladder. When the bladder was the seat of a new growth its presence might sometimes be determined by bimanual palpation with one finger in the rectum, or by examination with an ordinary searcher or sound.

The value of an examination with the electro-cystoscope in cases of hematuria in which the diagnosis was difficult could hardly be overestimated. By its aid we were enabled not only to distinguish with exactness the portion of the bladder from which the haemorrhage emanated, but also to determine the cause and extent of the lesion. The instrument was especially valuable in making a correct diagnosis in renal haemorrhage, for with its aid not only were we able to ascertain that the blood was derived from the kidney, but also to tell definitely on which side the affected organ was situated.

In ascertaining the precise source of haemorrhage from the kidney, the clinical symptoms, the physical signs, and the previous history of the patient were usually of great value, although haemorrhages occasionally occurred without the slightest warning and without other symptoms. As a rule, however, symptoms were present which point to the kidney as the seat of the difficulty. Lastly, if for any reason it was impossible to detect the situation of the lesion, and at the same time the bladder appeared to be its most probable seat, it was perfectly allowable to perform an exploratory suprapubic cystotomy, especially if the haemorrhage was severe or had been of long duration.

Dr. W. F. Glenn, of Nashville, said that by means of the Leiter cystoscope and the Otis urethroscope we could often make out with certainty whether the source of the bleeding is the urethra, the bladder, or the kidney.

Dr. Baysox said that, while he was inclined to agree to the statement made by Dr. Glenn, we still needed an instrument which would enable us to get a good view of the vesical outlet. The speaker called attention to the possibility of determining the source of pyuria, when it was unilateral and of renal origin, by means of the cystoscope. He had catheterized the ureters in women, but regarded it as a very uncertain procedure; at least it had been in his hands. When properly and skillfully used, there is probably no instrument which afforded the same amount of diagnostic advantage as the cystoscope. To use the instrument well required long practice, and the photographs of cytoscopic views which were now accessible were among the very best aids we had in studying the vesical interior.

Dr. Edward R. Palmer, of Louisville, said he had had no trouble in getting a view of the bladder neck, for which purpose he employed a long Klotz tube (No. 24 to 26) and the Otis instrument lamp.

Dr. Aner Post, of Boston, referred to two cases of carci-noma of the kidney that had recently come under his observation in which some very interesting casts of the ureter had been seen. In one case there had been a large number of very short casts, while in the other there had been one continuous cast over five feet in length.

Dr. Robert W. Taylor, of New York, asked Dr. Palmer whether he had not found that the introduction of such large instruments into the posterior urethra was apt to give rise to epididymitis.

Dr. Palmer replied that he had never seen any untoward results follow the introduction of the long Klotz tube.

Dr. Otis said that, while the cystoscope is of great value in detecting the source of haemorrhage from the genito-urinary tract, there were certain cases in which it could not be used because of the free bleeding, or because the bladder was very small. He agreed to the statement made by Dr. Bryson that in cystoscopy we were not able to get a good view of the internal urethral orifice.

Gonorrhoea in Women.—Dr. Taylor read a paper on this subject. He stated that gonorrhoea in women was certainly much less frequent than it was in the male, and usually ran a much less definite course. In the main, it localized itself in one or two parts, ran an acute course, became subacute, and ceased. In many cases it began and remained in a subacute condition for a considerable time. Then, again, in some cases it progressively invaded the genital tract. Having become lodged in the cervix uteri, it might extend to the body of that organ and attack the Fallopian tubes and the ovaries, and then the peritoneum. Patients thus affected were usually sterile, they suffered intense discomfort and pain, and their health was so impaired that they might become mental and physical wrecks. These sad results certainly did occur in relatively quite a large number of cases. Instances were not infrequent in which wives were infected with gonorrhoea by their husbands, who perhaps regarded themselves as cured. It was very difficult and even impossible to get reliable statistics as to the frequency of the occurrence of acute gonorrhoea in women. It of course existed largely in prostitutes, particularly in quite young ones, and those of the lower walks of life, and it was not uncommon in shop girls and others who, for various reasons, had left their homes and ceased to be under parental and family restraint.

In the light of recent investigations and studies it had been clearly proved that in women over twenty years of age the urethra and the cervix uteri were the parts most commonly attacked by gonorrhoea. There could be no doubt of the existence of a true gonorrhoeal infection of the vulva, but it was not very common. It was sometimes met with in young girls between fifteen and twenty years of age, usually as a result of their first infection and in their earlier attempts at intercourse. Although the existence of gonorrhoeal clytritis had been denied, there could be no doubt that in a restricted number of cases gonorrhoea primarily attacking the vagina did occur. It was also not infrequently infected by the gonorrhoeal secretion from the os uteri.

Gonorrhoea in women, as in men, consisted of an exudative inflammation of the submucous connective tissue, and the genital organs of women were so extensive, so complex, so involved, and so profusely supplied with blood-vessels which frequently underwent normal engorgement, that it could readily be understood why the morbid process might show a tendency to become chronic.

There had been a disposition developed within the past ten years to refer, in a loose and unscientific manner, all ailments peculiar to women to gonorrhoea, and to attribute to many husbands who in their earlier days had had gonorrhoea a gonorrhoeal-infection of their wives which produced serious consequences. The extreme and exaggerated views of Noeggerath, who had maintained that eight hundred out of every one thousand men living in large cities suffered from gonorrhoea, to which they never recovered from, and that, suffering or later infected their wives, had done much to perpetuate these ideas. There was a tendency nowadays to harp upon the longevity of the gonococcus, its phœnixlike power of resurrection, and its relentless virulence. This idea, put forth by some syphilographers, had had undue weight with many gynaecologists, who, under its influence, had been led to think that the gonococcus never died and that it was ever ready to
produce pelvic mischief. The author said he had seen many young women who had suffered from uterine and pelvic disease after marriage, whose trouble had been induced by instrumental manipulation at the hands of energetic young men possessed of an ambition to be known as gynecologists. Minor surgery was certainly the cause of many cases of uterine and pelvic disease. In estimating the importance of gonorrhoeal infection as a cause of trouble in women we must individualize rather than generalize.

Dr. Palmer said it had been stated, and correctly, that in these cases of diseased Fallopian tubes, of long standing, and containing large quantities of stagnant pus, the latter very frequently failed to show the presence of gonococci. On making a section of the structure of the tube itself, however, the gonococci would be found living in the stroma. They possessed a tendency to burrow under the surface. In one case of monocytophthirism that had come under his observation there had been gonorrhoeal infection of the incarcerated testicle, which had become so painful that it had had to be removed at the height of the inflammation. The gonococci had been found in the intimate structures of this organ, which was of course rudimentary.

Dr. Glenn expressed the opinion that the gonococci, unless it became imbedded in the mucous membrane, was not a difficult micro-organism to kill.

Dr. Lewis said that Wertheim’s experiments had clearly shown the penetrative power of the gonococci.

*(To be continued.)*

### Book Notices.

This is a very useful directory of the health resorts and sanatoria of Germany, Austria, Switzerland, and the adjoining countries, preceded by about fifty pages devoted to the climatic and balneological indications in various diseases. The physician who is called upon to select a place of sojourn for an invalid may often derive material aid from consulting it.

**BOOKS, ETC., RECEIVED.**

Text-book of Operative Surgery. By Dr. Theodor Kocher, Professor of Surgery and Director of the Surgical Clinic in the University of Bern. Translated with the Special Authority of the Author from the Second Revised and Enlarged German Edition, by Harold J. Stiles, M.B., F.R.C.S. Edin., Senior Demonstrator of Surgery and formerly Demonstrator of Anatomy in the University of Edinburgh, etc. With One Hundred and Eighty-five Illustrations. London: Adam and Charles Black, 1895. Pp. xviii-393. [*Price, 3s. 6d.*]

The Lumleian Lectures on Certain Points in the Pathology of Disease. Delivered before the Royal College of Physicians, to which is added the Harveian Oration, delivered before the College in 1893. With a Biographical Notice of Harvey and an Appendix of Statistical Tables. By P. H. Pye-Smith, M.D., F.R.S., Fellow of the College and Senior Physician to Guy’s Hospital. London: J. & A. Churchill, 1895. Pp. 256. [*Price, 7s. 6d.*]

The Care of the Baby. A Manual for Mothers and Nurses, containing Practical Directions for the Management of Infancy and Childhood in Health and in Disease. By J. P. Crozer Griffith, M.D., Clinical Professor of Diseases in Children in the Hospital of the University of Pennsylvania, etc. Philadelphia: W. B. Saunders, 1895. Pp. 3 to 392. [*Price, $1.50.*]

Transactions of the American Association of Obstetricians and Gynecologists. Vol. VII. For the Year 1894.

Transactions of the Southern Surgical and Gynecological Association, Volume VII. Seventh Session, Charleston, S. C., November 13, 14, and 15, 1894.

Annual Report of the Department of Health of the City of Chicago, for the Year ending December 31, 1894.

Transactions of the Massachusetts Medico-Legal Society, Volume II, No. 5, 1895.

A Rapid Method of Making Permanent Specimens from Frozen Sections by the Use of Formalin, by Thomas S. Callen, M. B. [Reprinted from the Johns Hopkins Hospital Bulletin.]

The Treatment of Opium Poisoning by Potassium Permanente. By William Moor, M. D. [Reprinted from the Medical News.]

Hypertrophied Pharyngeal Tonsil as the Exciitant in Suppurative Otitis. By M. D. Lederman, M. D. [Reprinted from the Manhattan Eye and Ear Hospital Reports.]

Suprapubic Cystotomy for Calculus of the Bladder. By A. H. Moischenbuehl, M.D., St. Louis. [Reprinted from the Journal of the American Medical Association.]

A Report of One Hundred and Eighteen Catarrh Extractions, with Remarks. By David Webster, M. D. [Reprinted from the Manhattan Eye and Ear Hospital Reports.]

Stricture of the Esophagus. By George F. Keiper, M. D. [Reprinted from the Fort Wayne Medical Magazine.]

The Medical Millennium. The Doctorate Address of the Medical Department of the University of Louisville, Session of 1894 to 1895. [Reprinted from the American Practitioner and News.]

Bicycling for Women.—In the Boston Medical and Surgical Journal for June 13th Dr. Charles W. Townsend has an article on this subject in which he states that he sent a list of questions to eighteen women physicians in Boston and throughout the State in regard to the value of bicycling for women. The replies, he says, seem to him to over the field of bicycling for women very satisfactorily, showing that the bicycle is of great value to the average woman, even to the woman with various forms of uterine disease. They also show that the bicycle when improperly used may do harm.

Outdoor exercise, he says, is of great value to every one, and women, as a class, suffer greatly from the lack of it. Another thing from which women suffer is too heavy and too tight clothing. Both of these ill the average woman is entirely unconscious of, and will deny the need of more exercise on the one hand, or the existence of heavy and tight clothing on the other. No amount of dress-reform preaching or of ephelistic exercises will remedy these evils or awaken the woman to a knowledge of the possibilities of the enjoyment of life. This is what the bicycle is doing, and is destined to do in the future.

The bicycle provides not only an agreeable method of exercise in the open air, but also demands a comfortable, loose, and light costume. Whether it will change woman's dress so far as to discard the skirt and substitute the divided garment or loose knickerbockers remains to be seen.

Patients who have substituted the comfortable loose health waists for corsets while they were riding, have found that corsets were unnecessary for their every-day dress and decidedly uncomfortable.

In talking with several ladies' tailors on this subject the author has found that short corsets which do not press on the abdomen are used, and that, while some cling to the regulation corset, many are using waists simply.

Like all forms of exercise the bicycle, he says, can do harm by excessive use. Too great speed or too long rides are exhausting and may injure some delicate point. The exercise is so agreeable and inspiring that there is more danger of excess than in many outdoor sports, especially if a spirit of ambition and rivalry is allowed. The long rides on time—"century" runs are indulged in by women—accomplish no useful purpose and often result in great harm.

Another danger to be avoided is the strain from riding up steep hills, a case where ambition often compels the rider to persist after the effort becomes too great. A good rule is to dismount and walk up every hill where the effort of riding is at all irksome. The change of exercise is restful and beneficial.

Another evil, says Dr. Townsend, one which fortunately is often not understood by parents, who think that the bicycle is so constructed as to require a bent posture. There is no more need to condemn bicycling on this account than there is to condemn horseback riding on account of the position of the jockey in racing.

The saddle, in addition, allows of considerable adjustment of tilting, and should be so arranged as to avoid pressure in the pudendal region. This danger has by some been much overestimated and can be avoided. The stooping posture, as well as a faulty position of the saddle, tends to bring pressure in this region.

The delightful nature of the exercise is of the greatest value. To most women gymnasia work is a bore, and so, often, is walking with no object in view except the exercise. Both of these forms of exercise when prescribed by the physician often accomplish but little, as the patient is not taken away from herself.

Not so with the bicycle, which breaks up morbid trains of thought, takes the patient away from herself, and in that way benefits every nervous or functional complaint. It is, moreover, an exercise which develops self-reliance, a virtue much needed by this class of patients.

Dr. Townsend thinks that bicycling is beneficial to women, not from any special effect on the pelvic organs, but because it is an agreeable, healthful form of exercise in the open air, a form which exercises the whole body and indirectly benefits special conditions. And the converse of this holds true, that as a general exercise bicycling is not harmful to the pelvic organs even when these are affected, unless the disease is so acute that any exercise as great as this is contraindicated.

In the same journal Dr. James R. Chadwick publishes an article entitled Bicycle Saddles for Women, in which he remarks that he finds no serious attempts has as yet been made to produce a saddle that shall be adapted to a woman's anatomy.

The bicycle saddle for men, he says, seems to have been modeled upon the saddle that was found suitable for men riding upon a horse, being merely reduced in most of its dimensions. This has answered most of the requirements, though often found to strike against the prostate gland or the pubic arch. When begun to ride they were given the same saddle, regardless of the fact that behind the pubic bone are the external genital organs so prominent as inevitably to rest upon the anterior projection of the saddle. The result has been that women have generally had great difficulty in having the saddle so adjusted as to be rendered comfortable—in other words, to avoid pressing unduly upon the vulva.

His inquiries have not enabled him to form definite conclusions, but he has made evident the fact that the saddles in most use require many adjustments to be comfortable to the generality of female riders; that some of the saddles are absolutely unfit for the use of women; and that the teachers have no definite ideas by which they can adapt the saddle to the use of women.

A woman's pelvis is broader than a man's, and the tubercles of the ischia are farther apart in women than in men, consequently the width of the rear portion of the seat needs to be greater. No such provision has been made. This is a matter, however, easily corrected when attention is called to it. The anterior projection of the saddle must be tilted downward so that it will not strike against the vulva. This, however, requires the most delicate adjustment, for if the saddle is tilted too far the slope of the seat causes the rider to slide forward as to rest almost entirely upon the anterior projection, and so defeat the object of tilting. Again, the seat may be shifted backward and forward upon the frame without tilting. When shifted backward, the action of the leg upon the saddle tends to
push the body backward and thus to insure that the ischia shall rest upon the saddle; but in this position the muscular action of the legs is less effective, which renders the work of propulsion greater.

From the foregoing, says Dr. Chadwick, it is evident that the adjustment of the present form of saddle to women is attended with great difficulty. It seems to him that the anterior projection of the present saddle should be dispensed with if possible. The problem is whether without the anterior projection the seat of the rider would be sufficiently secure. The trouble is that when the leg is straightened and the tarede is at the lower point of its circuit the thickness of the thigh tends, by pressure on the anterior margin of an oval saddle, either to lift the tuberosities of the ischia from the saddle or to drag them forward, so that after a jolt they will not descend upon their proper place, and a secure seat will thereby be lost, or the skin is chafed at the junction of the thigh and the ischiadic region.

The feasibility of such a saddle as this, says the author, can be determined only by experiment, and this should be done before women are generally allowed to ride.

Dr. Chadwick thinks that bicycling is a most desirable form of recreation and exercise for women, and his purpose in bringing the subject up for discussion is to stimulate the inventive minds of its advocates to devise a saddle which shall not inflict local injury or discomfort upon women riders.

The Hysterical Breast.—In the Nouvelle iconographie de la Salpêtrière for March and April there is a long and interesting article on this subject by Professor Gilles de la Tourette, who remarks that this affection should be ranked among the trophic troubles allied to hysteria and closely connected with oedema. It constitutes, he says, one of the most interesting manifestations of the neurosis, especially from a surgical point of view. The hysterical breast has led to many errors in diagnosis, followed occasionally by the ablation of an organ which, under the circumstances, was amenable only to medical intervention.

Willis, at the end of the seventeenth century, seemed to be the first to observe this manifestation. A young woman was attacked with very violent hysterical symptoms following a blow on the breast. The swelling of the organ and the pain were coincident with the convulsions. After pregnancy, however, the hysteria, with the swelling and the pain, disappeared. Frederic Hoffman, in 1748, reported two cases of painful swelling of both breasts coincident with hysterical attacks. At the end of the last century M. P. Pomme said: "The breast swells occasionally from the effects of the reflux of menstruation, and often this swelling has been mistaken for a true tumor. It is painful, and is a source of great alarm to the patient. Too much air in the cellular tissue of the breasts and the engorgement of the mammary veins from the reflux of the hypogastric region give rise to this error. The application of a wet cloth usually arrests the symptoms." Watson said that surgeons were well acquainted with the hysterical breast. The breast becomes painful and sensitive, and increases somewhat in size. In 1837 Brodie made a distinction between the cases of hysteria and those of tumor. Although his opinion on this point is erroneous, says the author, his description of the hysterical breast is not without importance, and is remarkable for its clearness. "Some young women," he says, "are subject to an affection of the breast which shows a great resemblance to the articular affections of an hysterical nature. The patient complains of a pain in the breast, and the least pressure causes her to cry out. Sometimes simply palpating the organ produces movements of the entire body, which resemble very much those of chorea; however, if the patient's attention can be completely turned from herself, not only will the movements cease, but she will scarcely feel any pain. This hyperesthesia is not limited to the breast; it extends to the axilla and to the arm. No tumor is found in the organ, but when the affection is somewhat advanced the breast becomes swollen, probably in consequence of a secondary hyperaemia. Nevertheless, there is no redness of the skin, rather, on the contrary, a slight pallor, with a generally shiny aspect. These cases must not be confounded with those of painful tumors of the breast, of which Astley Cooper gives illustrated examples in his work. It is also necessary to distinguish them from all kinds of tumors presenting themselves in women who are not in any way predisposed to hysteria. In these cases the pain and the sensitiveness are much less than in those of true hysteria." Brodie's description is excellent, says the author, with the exception of a few points, particularly in regard to the fact that hysteria may produce veritable tumors in the breast that may lead to errors in diagnosis.

Hysterical breast, says M. de la Tourette, like arthralgia, is a type of local hysteria. In its atiology, contusion of the organ will often be observed. The local traumatism influences the mental state of the patient, who is only too ready to favor this localization. Apart from these cases where the occasional cause may be recognized, there are others in which we have only the common aetiology of hysteria. The symptoms often exist in women who suffer with painful menstruation, who present hyperesthetic or hysterogenic of the vagina or of the neck of the uterus. It is certain that disturbances of the latter may singularly influence the organs of lactation and produce there hysteria. Nearly always one breast alone is attacked, although Frederic Hoffman and Liouville have observed cases where the two breasts were involved at the same time.

The hysterical breast consists of a temporary or permanent increase in the size of the organ with considerable hyperesthesia of the skin. It is a question of a hyperesthetic, hysterogenic zone the excitation of which leads, in the majority of cases, to convulsive paroxysms. At the moment of the attack a series of vaso-motor symptoms are produced locally which begin with simple congestion and lead to edema, sometimes, perhaps, to gangrene of the skin. Hyperesthesia of the skin of the breast does not differ from that of the skin of other parts of the body. It is much more marked when a slight, superficial friction is applied; sometimes it is so exquisite that the patients cannot bear their clothing to touch them, although in certain cases the pressure of the corset seems to give relief.

The hyperesthesia is permanent, but it is more marked at certain times under the influence of causes which usually control the excitation of the hyperesthetic zones that are transformed into hysterogenic zones. Direct pressure and acute emotions may cause the zone of the breast to become active in the same way that it feels the influence of the excitation of the neighboring zones or of those which, situated near the vagina or the uterus, become excited during menstruation. At the moment when, under the action of these various causes, the zone of the mammary region becomes excited, it or the breasts become spontaneously the seat of a prickling sensation and of darting pains which are very severe and of a neuralgic character. The breast becomes tumid, the nipple is erect, and the entire organ increases to almost double its size. Frequently the pain does not remain localized, but radiates to the axilla, to the spine, etc. The skin at this period, according to Brodie, is not red, but somewhat pale and shiny. Liouville said that it was hot, red, and tense. Féré held the same opinion. The aspect of the skin may be variable, according to the cases, during the paroxysms or in the intervals. The tumefaction and other symptoms are not always limited to the duration of the paroxysm itself. In simple cases, or when the affec-
tion is just beginning, the swelling disappears with the painful attack, but more frequently, especially if the attacks follow each other closely, the tumefaction persists in variable degrees during the intervals between the paroxysms, and the attacks are always accompanied by this exquisite cutaneous hyperesthesia, which is excited under the influence of various causes. In these cases palpation reveals interesting peculiarities. During the attack it is almost impossible to palpate the breast. The pain is much too acute to admit of a reliable examination. But it is not so in the intervals between the paroxysms, especially if care is taken to palpate the gland deeply and not superficially, as the cutaneous irritation is likely to produce excitation of the hysterogenic zone.

Hysteria of the breast, says M. de la Tourette, is very tenacious, and its duration may be very long. It is known, moreover, how difficult it is sometimes to remove a mark of the nature of a hysterogenic zone, and the hysterical breast is nothing else than the reaction of a special organ under the influence of a zone of this kind.

This affection is perfectly characterized and depends on the hysterogenic and hysterogenic zone of the skin of the mammary region and on an oedema of the connective tissue of the gland, which may assume a white, a red, or the violet color of hysterical edema. Apart from this form, where the swelling of the breast is uniform, there is another form susceptible of the same interpretation. In this the edema is hard and is localized more particularly in certain points under the form of tumors which are not accompanied by ganglionic engorgement unless there is ulceration.

If these peculiarities are considered, says the author, the diagnosis should scarcely be doubtful, although amputation has been practised several times, and it is still advised at the present day. M. Pean, he says, practised partial amputation of the breast in a young hysterical girl in whom palpation had revealed some nodes. The pains persisted after amputation, however, becoming more violent during the hysterical attacks, which were coincident with menstruation. This fact, says M. de la Tourette, proves that surgical intervention should be condemned. The author has ascertained, moreover, that the microscope does not reveal anything abnormal in the amputated part except a slight proliferation of the glandular elements.

The author relates the histories of two cases from which the conclusion may be drawn that the prognosis of hysterical affection of the breast is relatively grave, since not only may it extend over a period of twelve years, as was shown in one case, but may give rise to gangrenous symptoms that may cause amenity and fistula by secondary infection.

Psoriasis Treated with Oil of Copaiba.—In the Therapeutic Gazette for June 15th Dr. J. Abbott Cantrell says that the use of copaiba oil in the treatment of psoriasis has shown such good results in his hands that he wishes to record the following cases, in which other treatment had been employed without the slightest abatement of the trouble until the copaiba was used: In the first case, the patient, a woman twenty-nine years of age, had always been healthy until the appearance of the psoriasis, which had first attracted attention in her seventeenth year. The disease had spread rapidly over the entire body, and at the time the author saw her her condition was as follows: The eruption occupied a great portion of the body surface, the lesions being small and large, some of which had coalesced, making very large areas of affected skin. The lesions ranged in size from that of a pinhead to a patch or two which were about seven inches or more in diameter upon the back and chest, while those upon the abdomen were nearly as large.

Those upon the extremities ranged from a pea-sized papule to lesions having a diameter of several inches, the latter of which had coalesced, forming an irregular lesion. All of the lesions were distinct, with abrupt edges, being covered with the characteristic silvery-white or mother-of-pearl incrustated scales.

The girl stated, and she was corroborated by her physician, that the disease had had no abatement since it was first noticed, although she had never been without treatment for it. She came under the care of her present physician, and was immediately brought for the author's advice in the matter of treatment. He found that she had been under almost all forms of treatment; and as the arsenic which she had been taking had made no alteration in the skin manifestation, he advised her to place herself under strict observation, and to take five minimis of oil of copaiba in capsules three times daily. A good nourishing diet and free access to open-air exercise were also prescribed. The case passed from his view, although he occasionally heard from the attending physician, and in the latter part of the sixth month of treatment the report was that she had not one lesion present, and, as that was some twelve or fourteen months ago, the author feels that the treatment is well worthy of attention. He thinks it well to make note of the fact that, as there were no distressing symptoms to the girl on account of itching, he did not advise any local measures, simply because she did not wish to be obliged to use ointments if there was a reasonable hope of her getting well without them, as that had been the main treatment which she had been under for the previous years, and she stated that it was very disagreeable to her.

In the second case the patient stated that the disease had existed for fifteen years, but that she had been continuously under the care of physicians, and that she had got some relief, but that the disease had never actually been cured. The eruption was found to occupy the back, the chest, and the head, and lesions were found scattered over the extremities. The lesions were papules as first witnessed, but they soon spread, until, at her visit to the author, he found some of the size of a banknote, while others had a diameter of seven or eight inches. The woman had always been in good health, and no one in her family had ever had the same condition. Since that time, however, the author has had her younger sister under treatment for the disease. When first seen by him she placed her upon five minimi doses of oil of copaiba, with instructions that she was to keep under strict treatment for at least three months, at which time he wished to see her again. She presented herself at the appointed time, when it was found that the condition was decidedly improved; in fact, there were no new lesions present, the old ones were faded in color, there was no scaling, and she was fairly comfortable. He saw her again only a few days before writing the article, and did not find a single lesion-present, so that he felt that at last she had received the proper treatment. Her sister had not continued the treatment for more than a month, but all the lesions had disappeared, and there had been no return of them.

Goose Grease.—In the June number of the Dublin Journal of Medical Science Mr. Laugford Symes, physician to the Kiltegan Dispensary, contributes an article in which he remarks upon the scarcity of the animal oils and oleaginous substances in the British Pharmacopoeia in comparison with those derived from vegetables, and he calls attention to the properties of an oleaginous substance of peculiar penetrating power, which for many years had been well known in most households.

At present, he says, there are but three animal oleaginous substances in the British Pharmacopoeia: Oeleum morrhuae, lard, and hydrous wool fat (lanolin). The one of which he
Two Cases of Mumps Accompanied by an Eruption.—

The *Vencou Mountellier medical for June 1st publishes an account by M. Merard of two cases of mumps that had come under the care of Professor Carrien. The cases presented a remarkable peculiarity, the disease being accompanied by an eruption. The first case was that of a soldier who was admitted to the hospital on the 17th of April with chills, headache, and insomnia. On the 18th the parotid regions were tumefied; the genial prolongation of the parotids was increased in size, and the glandular congestion was very easily seen. The pain was rather pronounced. The submaxillary glands were not involved, and the fever was not high. The treatment consisted of inunctions of the parotid region. On the 19th the face was congested and the eyes were injected and watery. There was some nasal super-secretion, with bronchial catarrh. A morbid eruption was noticed; the spots were of about the size of a grain of rice and slightly prominent, and disappeared on pressure. They were seen only on the body and the limbs. Deglutition was painful. The tonsils, the pillars of the fauces, and the palate were intensely congested. There was no ganglionic engorgement and no fever. On the 20th the condition of the patient was the same, and there was no albumin in the urine. On the 21st the eruption had lost its redness, there was apyrexia, and the catarrh of the mucous membranes had disappeared. On the 22d there was tumefaction of the parotid regions, with a little pain, and the angina persisted, although it was very slight. There was very little desquamation. From this time until the 2d of May the patient's condition remained the same, when the engorgement was very much diminished. The left testicle was painful, and in the evening the temperature rose to 103° F. On the 3d of May the left testicle was increased in size and very painful. The skin of the scrotum was red and tense; the temperature was 101°6 in the morning and 104°9 in the evening. On the 4th the testicular pain persisted, but the temperature had fallen to 101°6. On the 5th there was apyrexia. On the 7th the testicular symptoms disappeared and the parotid regions regained their normal size. On the 10th recovery was complete.

The second case was also in a soldier who entered the hospital on the 17th of April with headache and lumbago. On the 18th the parotid engorgement was very marked. The submaxillary glands were not attacked. There was no ganglionic engorgement and no fever. The treatment was the same as that employed in the first case. On the 19th the face was congested. The eyes were watery, but there was no nasal or bronchial catarrh. Deglutition was difficult. The tonsils, the pillars of the fauces, and the velum of the palate were hyperemic, and a morbid eruption was observed, in every way resembling that in the preceding case. On the 20th there was no fever. On the 21st the eruption had nearly disappeared and the apyrexia continued. On the 22d there was slight desquamation, and the parotids had diminished in size. On the 25th the patient was completely cured.

The first case, says the author, was manifestly one of mumps, as was proved by the coincident orchitis accompanied by a high fever. With regard to the eruption, he asks, should it be attributed to an intercurrent measles which had broken out at that time in the regiment? Nothing would seem to warrant such a diagnosis, he says, because the fever was absent or only very slight up to the moment when the testicular symptoms appeared, when all symptoms of measles had disappeared. The course of the eruption also shows that it could not have been measles, as there was no trace of it on the face of the patient. None of the characteristics of this disease were present, and everything pointed to a mumps eruption.

The second patient presented no symptoms of orchitis. If,
MISCELLANY.

Says M. Merard, as in the first case, we entertain the idea of measles in association, the apyrexia and the course of the eruption being taken into consideration, may we not see there the syndrome of simple rubeola with subauricular engorgement? It may also be added, he says, that it is the ganglia of the parotid that are attacked and not the parotid itself. The engorgement also is slight, not easily seen, and never becomes localized in the genian prolongation of the parotid.

In these cases there was no reason to suspect syphilitic rosolia, and the medication was not of a nature to give rise to an eruption, therefore, says M. Merard, it must be concluded that the eruption was a cutaneous manifestation of the mumps. This, he says, is not at all surprising, as at the present day the exanthem of eruptive fevers is considered the result of the elimination by the skin of the toxines which are secreted by the infectious agent of the disease. In mumps the emunctories are the salivary glands, sometimes the testicles, and more rarely the breasts, the ovaries, and the lacrymal glands.

These mumps eruptions seem comparable to those which were observed during the epidemic of gripppe in 1892 by Professor Carrion. There is, however, a difference. The gripppe eruptions are not met with except in the gastro-intestinal form of the disease. They appear to be due to the elimination of toxines produced in the digestive canal, the secretions of which are disturbed or altered, and not to the grippel toxines themselves. In the preceding cases of mumps, on the contrary, where the gastric disturbance was insignificant, the eruption clearly seemed to be due to the toxines themselves of the bacillus of Catrin.

**Dissolving Views (Medico-Idyllic).** By F. A. Burrall, M. D.:

When comets flamber their candate brands
And make the August furnace hotter,
When like sere Unnyanymba's sands
Glow city walls from roof to gutter,
When dogs delight to bark and bite,
With Sirias beams upon them focused,
But find an end to gruesome flight
In murderous blows from watchman's locust,
Then where the mountains cast their shade,
Where silvery surfs the beaches hammer,
Where blend the brooklet with the glade,
Roam civic youth and civic maid
Away from civic dust and clamor.

As if confounded in heated cell,
Sits a sad son of Esculapius,
There's no escape he knows full well,
For him there is no corpus habens;
The fervid sun mounts up the sky,
And bids aloft the rising column—
It marks the nineties—with a sigh.
He smiles, but ah, that smile, how solemn!
There comes a vision from the north
Of ices, icebergs, congelation,
But what is all the fancy worth?
Its end is only perspiration.

So far, so near, anon he hears
The muffled drum beat at life's portal,
And waits for Nature's "Forward march"
Through mortal life to life immortal.
One weary brain with hopes and fears
And yearnings vague the hours encumbers,
Casts horoscopes for future years,
And weeps and smiles and wakes and slumbers.

Hark the bells!
Doctors' bells!
What of woe or what of woe their clamoring foretells!
Ringing out at night
When the moon is bright,
When the ground is white,
When the voices of the rain
Chat athwart the pane!
Ringing madly, whether
Foul or fair the weather,
Ringing as in grief
For relief,
Calling to the street
Weary feet—
Calling, pleading, urging,
Doctors' bells.

From pain to pain, from tears to tears,
To joys and tears kalideoscope,
To life with all its hopes and fears
I bid thee welcome, mild exotic,
Unfolded atom, choicest type
Of quickened protoplasmic essence,
Come, for the hour is fully ripe,
The world awaits thine expected presence!

Sic dixit Esculapius, and
Half sadly, yet with cordial greeting.
He grasped the novice by the hand,
On this, the primal birthday meeting,
Began the starward march, begun,
The swift-winged markings on the dial,
Life's tangled labyrinth begun,
Its hours of joy, its hours of trial.

Ereit Esculapius, and
Sleep fell on tired babe and mother,
The smaller in the larger hand,
Each clinging closely to the other.
As in a dream the doctor sees
Murillo's babe,* whose argent glory
Mingles with the angelic note
Of eastern clime and eastern story.

Out to the street, the still, gray street
Downward the drowsy moon is viewing,
Where fierce and feline warriors meet,
And bacillary hosts are stowing.
To home, to bed, to sleep; say who
Better than weary doctor knoweth
The rest which comes like heavenly dew.
The blessed balm which sleep bestoweth.

A lake where fin and feather meet,
An air just right for oxygenation,
A rod, a gun, outfit complete,
A doctor, and a good vacation.

The New York County Medical Association held its general meeting on Monday evening, the 17th inst. The special order was as follows: State Medicine: The Physician as a Citizen, by Dr. Douglas H. Stewart (discussed by Dr. A. B. Daynard, Dr. Frank Van Fleet, Dr. C. B. White, Dr. G. D. McGurran, and others); Living Greek: the Language of Physicians and Scholars; a Language Easily Acquired, by Dr. Achilles Rose. Pathological specimens were presented.

THE NEW YORK MEDICAL JOURNAL.

A WEEKLY REVIEW OF MEDICINE.

EDITED BY
FRANK P. FOSTER, M.D.

The physician who would keep abreast with the advances in medical science must read a live weekly medical journal, in which scientific facts are presented in a clear manner; one for which the articles are written by men of learning, and by those who are good and accurate observers; a journal that is stripped of every feature irrelevant to medical science, and gives evidence of being carefully and conscientiously edited; one that bears upon every page the stamp of desire to elevate the standard of the profession of medicine. Such a journal fulfills its mission— that of educator—to the highest degree, for not only does it inform its readers of all that is new in theory and practice, but, by means of its correct editing, instructs them in the very important yet much-neglected art of expressing their thoughts and ideas in a clear and correct manner. Too much stress can not be laid upon this feature, so utterly ignored by the "average" medical periodical.

Without making invidious comparisons, it can be truthfully stated that no medical journal in this country occupies the place, in these particulars, that is held by THE NEW YORK MEDICAL JOURNAL. No other journal is edited with the care that is bestowed on this; none contains articles of such high scientific value, coming as they do from the pens of the brightest and most learned medical men of America. A glance at the list of contributors to any volume, or an examination of any issue of the JOURNAL, will attest the truth of these statements. It is a journal for the masses of the profession, for the country as well as for the city practitioner; it covers the entire range of medicine and surgery. A very important feature of the JOURNAL is the number and character of its illustrations, which are unequaled by those of any other journal in the world. They appear in frequent issues, whenever called for by the article which they accompany, and no expense is spared to make them of superior excellence.

Subscription price, $5.00 per annum. Volumes begin in January and July.
